CETYL, SULPHATE (ACID) OF. *Cetylsulphuric acid. Sulphocetic acid.* $C^{16}H^{34}SO^4 = \left.\begin{matrix}(SO^2)'' \\ C^{16}H^{33}.H\end{matrix}\right\}O^2$.—Produced by mixing sulphuric acid with cetylic alcohol at the temperature of the water-bath (Dumas and Péligot, *loc. cit.*) According to Köhler (*loc. cit.*) and Heintz (*loc. cit.*) the most abundant product is obtained by mixing the two substances at the lowest temperature at which they will act, viz. at the melting point of cetylic alcohol; dissolving the mixture in alcohol and saturating with potash; separating the precipitate from the liquid; concentrating the latter; treating the residue with ether, which extracts undecomposed cetylic alcohol, and leaves cetylsulphate of potassium; and repeatedly crystallising the latter from boiling alcohol.

Cetylsulphate of potassium forms white nacreous laminæ, consisting of interlaced microscopic needles; it is moderately soluble in hot alcohol, less in boiling water, insoluble in ether. It is not fusible. Heated to 140° C. with cyanide of potassium, it yields cyanide of cetyl.

CETYL, SULPHIDE OF. $(C^{16}H^{33})^2S$.—Prepared by the action of chloride of cetyl on an alcoholic solution of monosulphide of potassium at the boiling heat. Chloride of potassium then forms and sulphide of cetyl rises to the surface of the liquid, where it solidifies on cooling. It is then washed with cold water, melted in boiling water, and repeatedly crystallised from a mixture of alcohol and ether, till the melting point becomes fixed at 57·5° C. It forms shining scales resembling those of cetylic mercaptan. It dissolves readily in ether, and in boiling alcohol, very sparingly in cold alcohol. The alcoholic solution forms a white precipitate with acetate of lead, also dissolved in alcohol. (Fridau, Ann. Ch. Pharm. lxxxiii. 16.)

CETYL, SULPHYDRATE OF. *Cetylic Mercaptan.* $C^{16}H^{33}.H.S$.—Prepared by treating sulphydrate of potassium dissolved in alcohol with an alcoholic solution of chloride of cetyl. The product contains a certain quantity of sulphide of cetyl. It is purified by adding acetate of lead, then water, washing with water, and digesting in ether, which dissolves the cetylic mercaptan and deposits it on evaporation in crystalline scales having a silvery lustre. It melts at 50·5°C., but solidifies again only when cooled down below 44°, assuming the form of interlaced dendrites. It is sparingly soluble in cold alcohol, easily in ether, somewhat less easily in boiling alcohol. When boiled with water it gives off a peculiar odour.

The cold alcoholic solution produces, after a while, white flocculent precipitates with the alcoholic solutions of silver-salts and of mercuric chloride; it does not precipitate the salts of lead, platinum or gold. Mercuric oxide does not act sensibly upon it, even at high temperatures. (Fridau, Ann. Ch. Pharm. lxxxiii. 18.)

CETYLAMINES. Bases formed by the substitution of one or more atoms of cetyl in place of hydrogen in a molecule of ammonia. *Mono-* and *di-cetylamine* are not known.

Tricetylamine or *Nitride of Cetyl.* $C^{48}H^{99}N = N(C^{16}H^{33})^3$.—This base is produced by passing ammonia-gas into iodide of cetyl heated to 150° C. A white precipitate of iodide of ammonium is then formed, increasing in quantity if the temperature be maintained for a while at 180°, and the substance which remains in the fused state is tricetylamine. It dissolves in boiling alcohol and crystallises in colourless needles, melts at 39° C. and solidifies in mammellated crystals on cooling.

The salts of tricetylamine are insoluble in water, but soluble in ether and alcohol, especially in the hot liquids. The *hydrochlorate*, $C^{48}H^{99}N.HCl$, crystallises from boiling alcohol in needles, which are less fusible but more soluble than the base itself. Potash added to the boiling solution separates tricetylamine in the form of a heavy oil. The *chloroplatinate*, $C^{48}H^{99}N.HCl.PtCl^2$, is a cream-coloured, almost pulverulent precipitate, insoluble in water, sparingly soluble in alcohol. (Fridau, Ann. Ch. Pharm. lxxxiii. 25.)

Cetylphenylamine, $N.H.C^{16}H^{33}.C^6H^5$, and *Dicetylphenylamine*, $N.(C^{16}H^{33})^2.C^6H^5$, are produced by the action of iodide of cetyl on phenylamine (*q. v.*)

CETYL-XANTHIC ACID. $C^{17}H^{34}OS^2 = \left.\begin{matrix}(CO)''\\ C^{16}H^{33}.H\end{matrix}\right\}S^2$.—This acid is known only as a potassium-salt, which is prepared by adding alcohol and hydrate of potassium to a saturated solution of cetylic alcohol in sulphide of carbon, heating the mixture a little below the boiling point of alcohol, then leaving it to itself for a while and decanting. The clear solution, on cooling, deposits light scales, which may be purified by washing with a small quantity of cold alcohol and dissolving in boiling alcohol.

The salt is white, tasteless, odourless, very hygroscopic and unstable. Its alcoholic solution gives a white precipitate with *mercuric chloride*; canary-yellow with nitrate of *silver*, blackening in a few minutes; white with acetate of *lead*, also blackening rapidly; white gelatinous with salts of *zinc*. Digested with hydrochloric acid, it yields cetylic alcohol. (Desains and De La Provostaye, Ann. Ch. Phys. [3] vi. 494.)

CEVADIC ACID. An acid existing in the seed of sabadilla (*Veratrum Sabadilla*, Ritz), and probably also in the root of white hellebore (*Veratrum album*), and of *Colchicum autumnale.* To prepare it, the oil extracted from sabadilla seeds by ether is saponified with potash; the soap decomposed by tartaric acid; the mixture distilled; the distillate neutralised with baryta; and the resulting barium-salt evaporated to dryness, and distilled with syrupy phosphoric acid. Cevadic acid then sublimes in white nacreous needles. It is soluble in water, alchohol, and ether, and smells like butyric acid; melts at 20° C. and sublimes at a temperature a few degrees higher. Its salts have a peculiar odour. The ammonium-salt gives a white precipitate with ferric salts.

CEVADIN or **HORDEIN.** A mixture of starch, cellulose, and azotised matter obtained from barley.

CEYLANITE or **CEYLONITE.** A ferruginous variety of spinel (Al^2MgO^2), from Ceylon, and other localities, having the magnesium more or less replaced by ferrosum, and the aluminium by ferricum. It is the *pleonast* of Haüy. (See SPINEL.)

CHABASITE. A mineral belonging to the zeolite family, and consisting essentially of hydrated silicate of aluminium and calcium, a certain portion of the calcium being however always replaced by potassium or sodium. It crystallises in forms belonging to the hexagonal system. Primary form, an obtuse rhombohedron, having the angle of the terminal edges = 94° 46′. It occurs in the primary form, and in the combination $R . -\frac{1}{2}R . -2R$. Ratio of principal to secondary axes = 1·086. Cleavage distinct parallel to R. Specific gravity 2·0 to 2·1. Hardness 4—4·5. Transparent and colourless, sometimes flesh-red, with vitreous lustre. Streak uncoloured. Fracture uneven. Brittle. Shrinks before the blowpipe to a blistered, slightly translucent enamel. It is perfectly decomposed when heated in the state of powder before the blowpipe. It occurs in scattered crystals in the fissures of some trap rocks, and in the hollows of certain geodes disseminated in the same rocks.

The composition of most varieties of chabasite is nearly represented by the formula $Ca^2O.Al^4O^3.4SiO^2 + 6aq.$, which (if $al = \frac{2}{3}$ Al), may be reduced to that of a metasilicate $(Ca\ al^2)Si^2O^6 + 3aq$. Sometimes, however, the amount of alkali is considerable, as in the fourth of the following examples, which approaches nearly to $\left.\begin{matrix}Ca^{\frac{1}{2}}\\Na^{\frac{1}{2}}\end{matrix}\right\}al^3Si^2O^6 + 3aq.$

Analysis *a* is of a specimen from Kilmalcolm in Renfrewshire, by Thomson; *b*, from Aussig in Bohemia, by Rammelsberg; *c*, from Annerode near Giessen, by Genth; *d*, from Port Rush in Ireland, by Thomson:

	SiO^2	Al^4O^3	Fe^4O^3	Ca^2O	Na^2O	K^2O	H^2O	
a . .	48·75	17·44	—	10·47	—	1·45	21·72	= 99·93
b . .	47·91	18·14	—	9·64	0·25	2·56	21·50	= 100·00
c . .	47·00	19·71	0·15	10·63	0·65	0·33	22·29	= 100·76
d . .	48·99	19·77	0·40	4·07	6·07	—	20·70	= 100·00

Sometimes, however, the proportion of silica is somewhat greater, and the composition is more nearly represented by the formula $2(Ca^2O.Al^4O^3).5SiO^2 + 12aq.$ or $(Ca^4al^{12}H^2)Si^9O^{27} + 11aq.$; and here again, the proportion of alkali-metal may be considerable, as in the variety called *acadiolite*, which may be represented by the formula $(Ca^{\frac{2}{5}}Na^{\frac{2}{5}}K^{\frac{1}{5}})^4al^{12}H^2Si^9O^{27} + 11aq.$ Analysis *e* is chabasite from Drottning Grufva near Gustassberg in Jemtland (Berzelius); *f* is *acadiolite*, from New Caledonia (Hayes):

	SiO^2	Al^4O^3	Ca^2O	Na^2O	K^2O	H^2O	
e . .	50·65	17·90	9·37	—	1·70	19·90	= 99·52
f . .	52·02	17·88	4·24	4·07	3·03	18·30	= 99·54

(*Rammelsberg's Mineralchemie*, p. 816.)

According to Dana, *Haydenite* from Jones' Falls in Maryland, is merely a ferruginous variety of chabasite crystallised in scalenohedrons.—*Phacolite* from Leipa in Bohemia is another mineral of similar constitution, but containing less water, viz. $(M^4al^{12}H^2)Si^9O^{27} + 9aq.$

CHÆROPHYLLUM. The fleshy root of *Chærophyllum bulbosum*, which is now coming into use in France as an article of food, has been examined by Payen (Compt. rend. xliii. 269), and compared with that of the potato (a yellow variety):

	Chærophyllum.	Potato.
Water	63·618 . . .	74·00
Starch, &c.	28·634 . . .	21·20
Cane-sugar	1·200	
Albumen and other nitrogenous substances .	2·600 . . .	1·50
Fat	0·348 . . .	0·10
Inorganic matters	1·500 . . .	1·56
Cellulose and pectin-substances	2·100 . . .	1·64

The comparison is evidently to the advantage of the chærophyllum. According to Polstorf (N. Arch. Pharm. v. Brandes, xviii. 176), the seeds of this plant contain an alkaloïd, *chærophylline*. Most species of chærophyllum are aromatic.

CHAILLETIA TOXICARIA. An ulmaceous plant possessing poisonous seeds.

CHALCANTHITE. Native sulphate of copper. (See SULPHATES.)

CHALCEDONY or *Calcedony*.—A variety of quartz exhibiting various shades of white, yellow, grey, brown, green, and blue. It has usually the subdued lustre of wax, and is transparent or translucent, some milk-white varieties being opaque. It occurs in mammillary and botryoïdal shapes, and as stalactites in cavities roofed or lined with it. According to Fuchs, it is true quartz with some opal disseminated through it. Varieties of chalcedony are: agate, carnelian, cat's eye, chrysoprase, flint, hornstone, onyx, plasma, and sand (*q. v.*) Common chalcedony occurs in the toadstone of Derbyshire, in the trap rocks of Fifeshire, the Pentland Hills, and the Hebrides; magnificent specimens also in Trevascus Mine in Cornwall, in Iceland, and in the Faroe Isles.

CHALCODITE. A hydrated magnesio-ferrous silicate found near Antwerp in Jefferson county, New York, and originally mistaken for cacoxene. It occurs in stellate globular masses, having a bronze-like aspect, or as a deposit upon red hæmatite; also in prisms with very distinct cleavage in one direction. Translucent, yellowish-brown to blackish-green, with somewhat lighter streak. Lustre metalloïdal; on the cleavage faces, metallic and nacreous. Very flexible in thin laminæ. Hardness 1 to 1·5. Before the blowpipe, it gives off water, and exhibits the reactions of iron. Hydrochloric acid does not act upon it in the cold, but when heated, decomposes it with separation of silica. (C. U. Shepard, Sill. Am. J. [2] xiv. 265.)

CHALCOLITE. See URANITE.

CHALCOPHACITE. Octahedral arsenate of copper. (See LIROCONITE.)

CHALCOPHYLLITE. Syn. with COPPER-MICA.

CHALCOPYRITE. Syn. with COPPER-PYRITES.

CHALCOSTIBITE. Native sulphantimonite of copper. (See WOLFSBERGITE.)

CHALCOTRICHITE. Native cuprous oxide. (See COPPER, OXIDES OF.)

CHALILITE. This name is applied to two minerals found imbedded in grey almond-stone, from the county of Antrim in Ireland. One of these minerals is amorphous, with conchöidal fracture; cream-coloured, with faint waxy lustre; translucent on the edges, with faint lustre on the streak; slightly unctuous to the touch, and adhering to the tongue. In water, it falls to pieces with decrepitating noise. It is decomposed by hydrochloric acid, with separation of pulverulent silica.

According to v. Hauer (Wien Acad. Ber. xii. 229) it contains

SiO^2	Al^4O^3	Fe^2O	Ca^2O	Mg^2O	H^2O		Total.
44·11	10·90	1·05	6·74	13·01	24·07	=	99·88

with traces of manganese and potassium, whence the formula: $4M^2O.Al^4O^3.6SiO^2 + 13H^2O$.

The other mineral (first analysed by Thomson), is a dense aggregate of concentrically fibrous spherules, of pale blood-red colour; glistening; translucent on the edges; of hardness 5, and specific gravity 2·24. It does not fall to pieces in water, and when decomposed by hydrochloric acid, yields a jelly of silica.

This mineral, analysed by v. Hauer (Wien Acad. Ber. xi. 18) gave:

SiO^2	Al^4O^3	Fe^4O^3	Ca^2O	Mg^2O	Loss by ignition.		Total.
38·26	27·71	trace	12·01	6·85	14·32	=	99·15

whence the formula $6M^2O.4Al^4O^3.9SiO^2 + 12H^2O$ (Kenngott, Jahresber d. Chem. vi. 826; vii. 842). Both minerals are orthosilicates, the formula of the first being reducible to $(M^8al^6H^{10})Si^6O^{24} + 7aq.$ which is of the form $6R^4SiO^4 + 7aq.$, and that of the second to $(M^4al^8)Si^3O^{12} + 4aq.$ or $3R^4SiO^4 + 4aq.$

CHALK. Friable carbonate of calcium, very abundant, and forming the upper member of the cretaceous group which occupies nearly the whole of the south-eastern part of England, and a considerable portion of the north of France. It is white and opaque, very soft, and without the least appearance of polish in its fracture. Specific gravity 2·4 to 2·6. It contains about 2 per cent. of clay, besides free silica. Some specimens, perhaps most, contain a little iron. Sometimes also magnesia and chloride of calcium occur in small quantities. It may be purified by trituration and elutriation, the ferruginous and siliceous particles subsiding first, while the pure chalk particles remain suspended: this purified chalk when dried is called *whiting*. Chalk is extensively used in agriculture, as an addition to soils which are deficient in lime.

The name *chalk* is also occasionally applied to other earthy minerals; thus *Black chalk* is a peculiar kind of slate, also called *Drawing slate*, which produces a black shining streak on paper, and is used in crayon drawing. *Red chalk* is a clay, coloured by oxide of iron.

CHALK STONES. Gouty concretions in the joints, so called from their resemblance to chalk. They consist mainly of uric acid.

CHALKOSINE. Syn. with COPPER-GLANCE.

CHALYBEATE WATERS. Mineral waters containing carbonate of iron dissolved in excess of carbonic acid (p. 785).

CHALYBITE. Native carbonate of iron (p. 784).

CHAMÆLEON MINERAL. Manganate of potassium. (See MANGANATES.)

CHAMÆROPS HUMILIS. The leaves of this palm are coated with wax, separable by alcohol into cerin and myricin. (Teschemacher, *Rochleder's Phytochemie*, p. 219.)

CHAMOISITE. A black earthy mineral from Chamoisin in the Valais, containing, according to Berthier (Ann. Min. v. 393), 14·3 per cent. silica, 60·5 ferrous oxide, 7·8 alumina, and 17·4 water (=100), with 15 per cent. of carbonate of calcium. It is perhaps a mixture of magnetic iron ore with a hydrated silicate of aluminium.

CHAMOTTE. A mixture of fire-clay and fragments of burnt pottery used for making fire-bricks, pipes, crucibles, &c. *Chamotte-stones* from the kaolin of Halle, were found by Wackenroder (Arch. Pharm. [2] lxxv. 27), to contain 85·00 per cent. silica, 11·33 alumina, 2·23 ferric oxide, and a trace of magnesia; loss by ignition 1·00.

CHAMPAGNE WINE is made from selected grapes, red and white, the must of which, after fermenting in the vats from 12 to 15 hours, is drawn clear off into the casks; it is racked off about Christmas, once more after four weeks, and then fined with isinglass, which treatment is also repeated. The new wine is put into stout bottles in the month of May, leaving about 2 inches empty under the corks, which are wired down; and the bottles are laid on their sides for the progress of the fermentation: from 6 to 10 per cent. of the bottles burst. This stage of the process is completed in September, when the bottles are placed on their mouths, and left so for fourteen days to let the sediment settle in the neck, which settlement is promoted by a slight shaking. By dexterous opening of the bottles, the muddy deposit is discharged, and they are then filled up with clear wine, corked afresh, and packed up for transport, the cork being covered either with melted resin, wax, or tin-foil. In seasons or districts when the must is not sweet enough, sugar is added by pouring a thimble-full of syrup (called *liquor*), into each bottle, the wine destined for Russia receiving a double dose.

A like procedure is followed in making the sparkling wines of Germany, as on the Moselle, and at Esslingen in Wurtemburg. Carbonic acid gas is frequently condensed by an air-pump into the other more or less factitious frothing wines of France and Germany. U.

CHANTONITE. A mineral said to exist in certain meteorites (*q.v.*)

CHARA FŒTIDA. The ash of this plant has been analysed by Schulz-Fleeth (Pogg. Ann. lxxxiv. 80). Two specimens of the dried plant yielded 54·58 and 68·39 per cent. of ash, the chief characteristic of which was the very large quantity of lime which it contained, viz. 42·7 per cent., which exists in it almost entirely in the form of carbonate. The water in which the plant grew yielded in 100 pts. 0·1618 pt. of solid matter, of which 0·104 consisted of carbonate of calcium.

CHARCOAL. See Carbon (p. 759); also *Ure's Dictionary of Arts, Manufactures and Mines*, i. 615).

CHATHAMITE. Native arsenide of cobalt. (See Cobalt.)

CHAVICA OFFICINARUM. One of the names of the plant which yields *long pepper*. (See Pepper.)

CHAY or **CHAYA ROOT.** The root of the *Oldenlandia umbellata*, which grows wild on the coast of Coromandel, and is likewise cultivated there for the use of dyers and calico-printers. It is used for the same purposes as madder, to which it is said to be far superior, giving the beautiful red so much admired in the Madras cottons. U.

CHEESE is formed from milk by coagulating it with rennet; separating the curd from the whey; compressing the curd in moulds, after it is duly seasoned with salt; and keeping this solidified milk in a cool place for some time, to allow it to undergo a kind of fermentation, by which it acquires the flavour and other well known properties of cheese. The chemical changes undergone by the casein in this process are little understood. The milk, before it is coagulated, should be heated to about 85° F.; then it receives the rennet—the infusion in water of the stomach of a new-born calf, commonly salted and dried to make it keep. The rennet effects its curdling completely in about an hour and a half. The curd is cut with a three-bladed knife; drained of its whey; broken down by hand or otherwise, subjected to compression; then comminuted more completely; put into its mould; and exposed to a graduated pressure, commonly under a heavy weight, but in large dairies by a screw press, which can be progressively tightened. The comminuted curd may be well salted by enclosing it in linen cloth and immersing it for one day or several days in brine. It is then drained, wiped, and set away in a cold room. Roquefort cheese is made from a mixture of sheep and goats' milk, and is ripened in a chamber or cellar having a very low temperature. U.

The following table exhibits the composition of several kinds of cheese, as determined by Payen (J. Pharm. [3] xvi. 279).

Composition of Cheese.

	Water in 100 pts.	Ash in 100 pts. of substance:		Nitrogen in 100 pts. of substance:			Fat in 100 pts. of substance.	
		normal.	dry.	normal.	dry.	ash-free	normal.	dry.
Cheese from Chester	30·89	4·78	6·88	5·56	8·00	8·59	25·41	36·61
„ Brie	53·99	5·63	12·08	2·39	5·14	5·85	24·83	33·29
„ Neufchatel	61·87	4·25	11·17	2·28	5·99	6·07	18·74	49·15
„ Marolles	40·07	5·93	9·91	3·73	9·24	6·92	28·73	47·95
„ Roquefort	26·53	4·45	6·06	5·07	6·91	7·35	32·31	43·98
„ Holland	41·41	6·21	10·61	4·10	7·01	7·84	25·06	42·78
„ Gruyères	32·05	4·79	7·05	5·40	7·96	8·59	28·40	41·81
„ Parmesano	30·31	7·09	10·16	5·48	7·87	8·76	21·68	31·12

The *ash* of two samples of cheese has been analysed by Johnson (Ann. Ch. Pharm. lxxviii. 119): *a*. Hand-cheese (*Hand-Käse*) from the neighbourhood of Giessen, *b*. Swiss cheese.

K^2O	Na^2O	Ca^2O	Mg^2O	Fe^4O^3	CO^2	P^2O^5	NaCl
4·85	7·33	2·55	—	0·11	0·03	13·68	72·47 = 101·02
2·46	3·67	17·82	0·81	0·17	0·08	20·45	55·37 = 100·83

The hand-cheese exhibited an alkaline reaction; gave off 46·35 per cent. water at 100° C; the dried substance yielded 12·86 per cent. nitrogen and 13·15 per cent. ash. The Swiss cheese yielded 44·70 per cent. water, and, after drying, 8·0 per cent. nitrogen and 11·36 per cent. ash.

On the preparation of cheese, see *Traité de Chimie générale, par Pelouze et Frémy*, 2me éd. vi. 213, and *Muspratt's Chemistry*, article CHEESE.

CHEIRANTHUS CHEIRI. *Wallflower.*—The fragrant flowers of this plant have a bitter taste like that of cress. They contain a substance which assumes a carmine colour in contact with sulphuric acid. The seeds contain myrosin, but no myronic acid. (*Rochleder's Phytochemie*, p. 98.)

CHELERYTHRINE. An alkaloïd existing in very small quantity in *Chelidonium majus* (Probst, Ann. Ch. Pharm. xxix. 120; xxxi. 250). It forms orange-red salts, and, according to Schiel (Sill. Am. J. [2] xx. 220), is identical with sanguinarine, $C^{19}H^{16}O^4$, the alkaloïd of *Sanguinaria canadensis*. (See SANGUINARINE.)

CHELIDONIC ACID. $C^7H^4O^6 = \left.\begin{matrix}C^7HO^3\\H^3\end{matrix}\right\}O^3$. (Probst. Ann. Ch. Pharm. xxix. 116.—Lerch, *ibid.* lvii. 273.—Hutstein, N. Br. Arch. lxv. 23.—Gm. xiv. 413.—Gerh. iii. 754).—This acid exists in all parts of *Chelidonium majus*, the common celandine, in the form of a calcium-salt, together with malic acid and another acid, probably fumaric: it is most abundant at the flowering time. To obtain it, the expressed juice is coagulated by heat and filtered. The filtrate is acidulated with nitric acid, and nitrate of lead is added in small quantities, as long as a crystalline precipitate falls, care being taken not to add too much either of the acid or of the lead-salt. The precipitate, which contains lime, is diffused in a large quantity of water and decomposed by sulphuretted hydrogen, which takes place slowly; the solution of acid chelidonate of calcium is neutralised with chalk and boiled with animal charcoal; and the neutral liquid is evaporated till saline crusts form. After cooling, white crystals are obtained, of a silky lustre, which are to be purified by repeated crystallisation. To separate the acid, the chelidonate of calcium thus obtained is dissolved in water, the solution precipitated with carbonate of ammonia, and the concentrated solution of chelidonate of ammonium mixed with twice its volume of moderately dilute hydrochloric acid. Chelidonic acid is then precipitated as a mass of crystalline needles, which are to be drained on a filter, washed, and purified by crystallisation from hot water.

Chelidonic acid thus prepared contains 2 at. water of crystallisation, $C^7H^4O^6.2H^2O$, which it gives off (amounting to 9·2 per cent.) at 100° C., or when left over oil of vitriol. By spontaneous evaporation it may be obtained in long needles containing 3 at. water (12·7 per cent.). It dissolves sparingly in cold, more freely in boiling water, the solution solidifying as it cools. According to Probst, it requires for solution 166 pts. of water at 6° C. and 26 pts. at 100°. It dissolves in hydrochloric and sulphuric acids more abundantly than in water, and in 700 pts. of 75 per cent. alcohol at 12° C.

The acid dried at 100° C. gives off 2·0 per cent. ($\frac{1}{2}$ at.) water at 150°, probably with partial decomposition. If the heat be continued, no further loss takes place short of 210°; but at that temperature the acid sustains a considerable though not determinable loss; between 220° and 225° decomposition takes place, the residue becoming soft, blackening, and giving off carbonic anhydride. The black mass, treated with water, yields an acid which crystallises in yellowish crusts. Chelidonic acid burns with slight detonation when heated in the air. It is scarcely attacked by strong nitric acid: but moderately dilute nitric converts it, with evolution of nitric oxide and carbonic anhydride, into another acid; malic acid does not appear to be formed. Chelidonic acid dissolves without decomposition in cold oil of vitriol; but on the application of heat, the solution becomes yellowish, and gives off gas-bubbles, assumes a fine purple-red colour at the boiling heat, but after long boiling, gives off sulphurous acid and acquires a dull undefinable colour. When the calcium-salt is boiled with potash, oxalic acid is produced. (Lerch.)

CHELIDONATES.—Chelidonic acid is a strong acid, dissolving zinc and iron, with evolution of hydrogen, and decomposing carbonates. It is tribasic, its salts being *trimetallic*, $C^7HM^3O^6$, *dimetallic*, $C^7H^2M^2O^6$, or *monometallic*, $C^7H^3MO^6$, besides a few acid salts containing $C^7H^3MO^6.C^7H^4O^6$.

The *dimetallic* chelidonates are formed when the acid is neutralised with a metallic oxide or a carbonate; with alkalis or their carbonates, trimetallic salts are apt to form. Most of the dimetallic salts are soluble in water and crystallisable; they contain several atoms of water, which are given off at or above 150° C.; the ammonium- and silver-salts, however, become anhydrous at 100°. Those which contain colourless bases are themselves colourless. They have no action upon litmus. The *monometallic* salts are produced by heating the dimetallic salts with about ⅓ of their weight of free chelidonic acid or a dilute mineral acid. If the acid is in excess, acid salts are produced. The monometallic salts are resolved by repeated recrystallisation into acid and dimetallic salts. The *trimetallic* salts are formed by treating the dimetallic salts with a caustic alkali or alkaline carbonate. Those which contain colourless bases have a fine lemon-yellow colour; those which are soluble impart a deep colour to the water. Most of them contain several atoms of water, which are not given off at 100° C. They have no reaction upon litmus. They are decomposed by continued contact with water; those of the alkali-metals absorb carbonic acid from the air and yield a dimetallic chelidonate and a carbonate.

The *acid* chelidonates crystallise from the solutions of the dimetallic salts in hot hydrochloric acid, in delicate needles or scales, which do not give off their water of crystallisation at 100° C. They redden litmus, and may be recrystallised, but give up their base when repeatedly treated with hydrochloric acid.

Chelidonate of Ammonium. $C^7H^2(NH^4)^2O^6$.—A boiling dilute solution of the dicalcic salt neutralised with carbonate of ammonium, filtered and evaporated, yields the ammonium-salt, on cooling, in snow-white silky needles. The solution abandoned to spontaneous evaporation, ultimately solidifies to a transparent mass, which when collected and drained on a filter, yields the ammonium-salt in long capillary crystals resembling a knot of the finest silver-white hair. It effloresces in contact with the air, gives off 14·23 per cent. (2 at.) water at 100° C., and then exactly resembles sulphate of quinine. (Lerch.) It does not give off ammonia, either when exposed to the air at ordinary temperatures, or when heated to 100°. Heated above 160°, it turns brownish and gives off carbonate off ammonium; the residue does not contain any other acid. By repeatedly evaporating the solution and redissolving the residue, it is converted into the acid salt. It does not form a trimetallic salt when treated with carbonate of ammonium or caustic ammonia. (Lerch.)

Chelidonates of Barium.—The *tribarytic salt*, $C^7HBa^3O^6 + 3aq.$ (at 100°), is obtained by mixing a hot solution of the dibarytic salt with ammonia, precipitating with chloride of barium, and quickly washing the precipitate with water. It is a lemon-yellow powder which does not give off water at 100° C. It absorbs carbonic acid from the air, dissolves sparingly in water, not at all in alcohol.

The *dibarytic salt*, $C^7H^2Ba^2O^6 + aq.$, is obtained by decomposing the corresponding calcium-salt with a soluble barium-salt, or by neutralising the aqueous acid with baryta or its carbonate. It is colourless, crystalline, and very brittle; soluble in water.

The *acid salt*, $C^7H^3BaO^6.C^7H^4O^6 + 2aq.$ is produced by dissolving the tribarytic salt in boiling hydrochloric acid.

Chelidonates of Calcium.—The *tricalcic salt*, $C^7HCa^3O^6 + 3aq.$ (at 100° C.) is prepared by boiling the dicalcic salt with ammonia, or by decomposing the sodium-salt mixed with ammonia with chloride of calcium. It is a yellow amorphous powder, very little soluble in water, insoluble in alcohol.

The *dicalcic salt*, $C^7H^2Ca^2O^6 + 3aq.$ (at 100°), occurs in *Chelidonium majus* (p. 847). It crystallises in silky prismatic needles, very little soluble in cold water, but easily in boiling water; insoluble in absolute alcohol. The solution does not affect litmus. The salt is not efflorescent, and does not part with its water of crystallisation below 150° C.

The *acid salt*, $C^7H^3CaO^6.C^7H^4O^6 + 2aq.$, obtained by decomposing the preceding with hydrochloric acid, crystallises in needles.

Chelidonate of Copper.—Green sparingly soluble prisms, obtained by evaporating a mixture of an alkaline chelidonate with sulphate of copper.

Chelidonates of Iron.—The aqueous acid dissolves iron, forming *ferrous chelidonate.*

Ferric Chelidonate.—$Fe^4O^3.C^{14}H^4O^{10} = 2C^7H\mathit{fe}^3O^6 + H^2O$.—The solution of iron in chelidonic acid passes to a higher degree of oxidation during evaporation, and deposits a dingy yellow precipitate. The disodic salt forms with aqueous sesquichloride of iron, a dingy yellow precipitate, somewhat soluble in acetic acid and in excess of sesquichloride of iron; it does not diminish in weight at 100° C., and if set on fire at one point, burns away with a sparkling light, leaving charcoal and sesquioxide of iron. (Lerch.)

When chelidonate of potassium is mixed with excess of sesquichloride of iron, the greater part of the ferric chelidonate remains dissolved; the pale yellow filtrate gradually assumes a darker colour, and ultimately becomes black-brown and opaque, but recovers its pale yellow colour after some time; on heating the liquid, the changes of colour take place more quickly. The dark brown liquid forms with ammonia a rusty brown precipitate, which becomes black when treated with a larger quantity of ammonia, probably from formation of protoxide of iron.

Chelidonates of Lead.—A *basic salt*, $2C^7HPb^3O^6.3Pb^2O$, is obtained by adding the diplumbic salt mixed with ammonia to basic acetate of lead.

The *triplumbic salt*, $C^7HPb^3O^6$, is produced by treating the diplumbic salt with ammonia, or by mixing a cold solution of dicalcic chelidonate with basic acetate of lead. Yellowish-white flakes are then deposited containing $\frac{3}{2}$ at. water ($2C^7HPb^3O^6.3H^2O$), which is given off between 150° and 160° C., the salt then turning yellow. If the solutions are mixed at the boiling heat, the anhydrous salt is produced at once in the form of a lemon-yellow precipitate, darker in colour if mixed with the preceding. It is decolorised and decomposed by acids. Insoluble in water and in alcohol, soluble in lead-salts.

The *diplumbic salt*, $C^7H^2Pb^2O^6 + aq.$, is deposited, on mixing the dicalcic salt with nitrate of lead, in small shining crystalline scales or slender needles, which are insoluble in water, soluble in lead-salts and in ordinary strong nitric acid, but not in fuming nitric acid.

Chelidonate of Magnesium.—Efflorescent needles, obtained by neutralising the hot aqueous acid with carbonate of magnesium.

Chelidonates of Potassium.—The *tripotassic salt* is deposited in yellow crystals from a solution of the dipotassic salt mixed with caustic potash. It has no alkaline reaction when pure, but absorbs carbonic acid from the air, and is converted into the colourless dipotassic salt. Boiled with excess of caustic potash, it yields oxalate of potassium.

The *dipotassic salt* is obtained by decomposing the dicalcic salt with carbonate of potassium.

A *chelidonate of calcium and potassium*, $C^7HKCa^2O^6$, is obtained by mixing a concentrated solution of the dicalcic salt with an equivalent quantity of carbonate of potassium. In a very dilute solution, the lime is immediately precipitated as carbonate.

Chelidonates of Silver.—The *triargentic salt*, $C^7HAg^3O^6$, is obtained by precipitating the tricalcic or the dicalcic salt, mixed with ammonia, with nitrate of silver. It is a yellow very unstable precipitate.

The *diargentic salt*, $C^7H^2Ag^2O^6$, is produced by dissolving oxide of silver in chelidonic acid, or by precipitating the dicalcic salt with nitrate of silver and heating to the boiling point. It then separates on cooling in long colourless needles resembling acetate of silver. It is permanent in the air at ordinary temperatures, and is not altered between 100° and 200° C.; decomposes with slight detonation between 140° and 150°. It dissolves in water, ammonia, and strong nitric acid, but not in alcohol.

Chelidonate of silver and calcium, $C^7HCaAg^2O^6$, is obtained by mixing a concentrated ammoniacal solution of the dicalcic salt with a concentrated solution of nitrate of silver, as a light yellow precipitate, which alters but little in drying, and is decomposed by water only after long continued boiling.

Chelidonates of Sodium.—The *trisodic salt* has not been obtained in definite form.

The *disodic salt*, $C^7H^2Na^2O^6 + 4aq.$, is prepared by decomposing the dicalcic salt with carbonate of sodium; care must be taken not to add too large an excess of the latter, which would give rise to the simultaneous formation of trisodic chelidonate, and a trimetallic salt containing both calcium and sodium, a reaction which is immediately indicated by the yellow colouring of the liquid.

The disodic salt is very soluble in water both hot and cold, and is difficult to crystallise. By slow evaporation, however, small prismatic needles are obtained, which effloresce slowly when exposed to air. They contain 21·16 per cent. water of crystallisation, of which 15·5 per cent. goes off, at 100° C., the rest between 150° and 160°.

The *monosodic salt*, $C^7H^3NaO^6 + 2aq.$, is obtained in slender needles by treating the disodic salt with chelidonic acid.

The disodic salt treated with boiling hydrochloric acid, yields slender needles or scales, which appear to consist of an *acid salt*, $C^7H^3NaO^6.C^7H^4O^6 + 3aq.$

Chelidonate of Strontium.—Slender needles obtained by dissolving the carbonate in chelidonic acid.

Chelidonate of Zinc.—Obtained by saturating the acid with oxide of zinc; it is crystalline, and has an acid reaction.

CHELIDONINE. $C^{20}H^{19}N^3O^3$ (?) (Godefroy, J. Pharm. Dec. 1824; Probst, Ann. Ch. Pharm. xxix. 123; Realing, *ibid.* 131; Will, *ibid.* xxxv. 113; Gerh. iv. 210.)—An alkaloïd contained in all parts of the *Chelidonium majus*, especially in the root. It is obtained by exhausting the root with water acidulated with sulphuric acid, precipitating by ammonia, dissolving the precipitate in alcohol acidulated with sulphuric acid, reprecipitating by ammonia, and treating the residue with ether, which dissolves chelerythrine (sanguinarine) and leaves chelidonine. To purify this product, it is dissolved in the smallest possible quantity of water acidulated with sulphuric acid; the solution is mixed with twice its volume of strong hydrochloric acid, which, after a while, throws down a granular precipitate of hydrochlorate of chelidonine; the precipitate is digested with ammoniacal water, which sets the chelidonine at liberty; and the base thus obtained is crystallised from strong alcohol — or better from acetic acid.

Chelidonine crystallises in small colourless tablets, insoluble in water, soluble in alcohol and ether. It melts at 130° C. to a colourless oil, and decomposes at a higher temperature. The crystals contain 2 at. crystallisation-water, which escapes entirely at 100° C. According to Will's analyses, the base dried at 100° contains 67·4 to 68·1 per cent. C, 5·6 hydrogen, and 12·2 nitrogen; the formula $C^{20}H^{19}N^3O^3$ requires 68·8 C, 5·4 H, 12·1 N, and 13·7 O. Water of crystallisation, by analysis, 46·5 to 5·13; by calculation 4·91.

Chelidonine dissolves readily in acids, forming salts which have a bitter taste and redden litmus. Its compounds with the weaker acids, such as the acetate, are decomposed by evaporation. Ammonia added to solutions of the salts throws down a bulky curdy precipitate, which after a while contracts into a granular crystalline mass. The salts are likewise precipitated by tincture of galls.

According to Probst, solutions of chelidonine are not poisonous.

Hydrochlorate of chelidonine is crystallisable, and dissolves in 325 pts. of water at 18° C. The *chloroplatinate*, $C^{20}H^{19}N^3O^3.HCl.PtCl^2$, is a flocculent, afterwards granular precipitate, yielding by analysis 17·42 and 17·60 per cent. platinum, the formula requiring 17·77.

The *nitrate* is sparingly soluble in water; the *sulphate* and *phosphate* are very soluble both in water and in alcohol: all three salts are crystallisable.

The *acetate* is obtained by decomposing the sulphate with acetate of barium: it is very soluble in water and alcohol, and dries up to a gummy mass.

CHELIDONINIC ACID. $C^7H^{10}O^6$? (Zwenger, Ann. Ch. Pharm. cxiv. 350). —This is another acid contained in very small quantity in *Chelidonium majus*. When the decoction of the plant acidulated with acetic acid, is treated with neutral acetate [or nitrate] of lead, chelidonic acid is precipitated, and chelidoninic acid remains in solution; and by treating the filtrate with basic acetate of lead, not in excess, decomposing the precipitate with sulphuretted hydrogen, evaporating the filtrate, extracting with ether, and again evaporating, chelidoninic acid is obtained in hard, mammellated, yellow crystals. It dissolves easily in water, alcohol, and ether, and separates from the aqueous solution in hard, white, anhydrous crystals, having the form of an oblique rhomboïdal prism. It has a strongly acid taste, decomposes carbonates, and dissolves iron, with evolution of hydrogen. It melts at 195° C.; its vapour is extremely irritating. With *nitrate of silver*, it forms a white, crystalline, sparingly soluble precipitate. *Nitric acid* converts the acid into oxalic acid. Zwenger assigns to crystallised chelidoninic acid the formula $C^{14}H^{11}O^{13}$; it may perhaps be $C^{14}H^{10}O^{12}.HO$, or $2C^7H^{10}O^6.H^2O$.

CHELIDOXANTHIN. A yellow bitter substance contained in the root, leaves, and flowers of *Chelidonium majus*. It is obtained by precipitating the juice with subacetate of lead, decomposing the precipitate with sulphuretted hydrogen, and exhausting the sulphide of lead with boiling water. It crystallises in confused needles, but more frequently forms a yellow friable mass. It is sparingly soluble in cold, moderately soluble in boiling water. The solutions are yellow and very bitter, and are not altered either by acids or by alkalis. (Probst, *loc. cit.*)

CHEMICAL AFFINITY. *Chemical Attraction, Chemical Force, Elective Attraction, Elective Affinity; Chemische Kraft, Verwandtschaft, Wahlverwandtschaft, Wahlanziehung; Affinitas, Attractio Electiva; Affinité.*—Affinity is that power by virtue of which bodies of dissimilar nature unite together to form compounds of definite constitution, which cannot be destroyed by mechanical agencies, and are, for the most part, dissimilar in properties to the elements from which they are produced. Whether this force is of peculiar nature, distinct from all others, or only a modification of the power which, under various circumstances, shows itself as light, heat, electricity, magnetism, mechanical force, &c., is a question still undecided. That it is intimately related to heat and electricity, is manifest from the whole range of chemical phenomena; indeed no chemical change can take place without a corresponding alteration in the temperature and electrical state of the bodies concerned. The conclusion to which the progress of discovery appears to tend, is that chemical action, heat, electricity, and all other manifestations of force result from certain movements in the ultimate particles of bodies, and are accordingly convertible into the other. This idea will be further developed in the articles HEAT, LIGHT, and ELECTRICITY; for the present, while we are treating of phenomena purely chemical, it will be convenient to speak of affinity as if it were a distinct force.

The terms affinity and chemical combination are not used by all writers in exactly the same sense. L. Gmelin defines affinity as "the power by virtue of which bodies of dissimilar nature combine together into a whole, which appears perfectly uniform to the senses, even when assisted by the most powerful instruments" (*Handbook*, i. 33). Accordingly he applies it to mixtures of liquids, as of alcohol and water, alcohol and volatile oils, &c., and to solutions of solids in liquids, as of salts in water, resins in alcohol, &c., as well as to combinations in definite proportion. Most chemists, however, make a distinction between mixtures and solutions on the one hand, and compounds formed in definite proportions on the other, restricting the term "chemical affinity" to the force, whatever it may be, that is concerned in the formation of the latter. In favour of Gmelin's view, it may be alleged that mixtures of liquids and solutions resemble chemical compounds, commonly so called, in these respects, that they are perfectly uniform in colour, density, refractive power, and other physical characters, and that the force which holds the heterogenous particles together in them is sufficient to resist any tendency to separate arising from difference of density (*e. g.* a mixture of water and alcohol, never separates into two layers, like oil and water), and can only be overcome by the same means as are applied to the destruction of the more intimate kind of combinations, viz. heat, or the superior affinity of another substance, as when resin is precipitated from its solution in alcohol by addition of water, or carbonate of potassium from its aqueous solution by alcohol.

There are, however, several well marked characters by which chemical combination of the more intimate kind, such as that of oxygen and hydrogen in water, hydrogen and nitrogen in ammonia, sulphur and mercury in cinnabar, &c., is distinguished from mere mixture or solution. These distinctions relate to the proportions in which the constituents of the compound are united, to the character of the compound, and to the circumstances attending its formation and decomposition.

1. As regards *proportion*. Mixture and solution follow a law of continuity. Miscible liquids, such as alcohol and water, may be mixed in any proportions whatever, and a solid dissolves in a liquid in all proportions, up to a certain limit, the point of saturation: but chemical combination, properly so called, takes place in certain definite proportions and no others. Thus hydrogen and chlorine unite only in the ratio of 1 pt. by weight of hydrogen to 35·5 pts. of chlorine; oxygen and carbon, only in the ratio of 6 pts. carbon to 8 and 16 pts. oxygen; nitrogen and oxygen, as 14 pts. nitrogen to 8, 16, 24, 32 and 40 pts. oxygen; lead and oxygen as 103·5 lead to 8, $10\frac{2}{3}$, and 16 pts. oxygen, mercury and sulphur as 100 mercury to 8 and 16 pts. sulphur, &c. &c. In all cases, indeed, the number of compounds formed by any two elements is definite, and combination never takes place in any intermediate proportions.

The law which regulates the proportions of the several compounds of the same two bodies is called the "Law of Multiples," and may be thus expressed: The several proportions in which two bodies, A and B, unite, may be represented by the formulæ $A + B$, $A + 2B$, $A + 3B$, . . . $A + nB$, or $2A + 3B$, $2A + 5B$, . . . $3A + 4B$, . . . or in general $mA + nB$; where m and n are integer numbers in most cases not exceeding 7, at least in inorganic compounds.* We have seen in the article ATOMIC WEIGHTS (p. 452), that it was the observation of these proportions which led Dalton to the idea of the atomic theory. In short, if the ultimate atoms of the several elements be supposed to possess certain invariable relative weights, and to unite and form chemical compounds by simple juxtaposition, in the proportion of 1 : 1, 1 : 2, 2 : 3, &c., the law just enunciated follows as a matter of course. It is possible that the distinction between true chemical combination and mixture may be found in this: that combination takes place between ultimate atoms; mixture between the physical molecules of bodies, which are complex aggregates of atoms.

2. As to the *character of the product*.—The properties of a mixed liquid, as the colour, taste, specific gravity, refracting power, &c., are always intermediate between those of its components. In solutions also, the dissolved body imparts to the solvent its taste and colour, in proportion to the quantity dissolved, the density of the solution also increasing regularly and continuously with the amount of solid matter taken up; but definite chemical compounds generally differ altogether in physical properties from their com-

---

* The combining proportions of the elements of organic compounds are regulated by much more complex laws. In the series of fatty acids, for example, we find the same quantity of oxygen (8 pts.) associated with 3, 2×3, 3×3, 4×3, 5×3, ... 30×3 parts of carbon; and if, in addition to this, we consider the various proportions of C, H, N, and O, existing in the numerous series of organic bodies, it may fairly be concluded that the constitution of these bodies would never have suggested the law of multiples, as above stated. Indeed, it is only by introducing the hypothesis of compound radicles, that the composition of organic bodies can be assimilated to that of inorganic compounds. (See ORGANIC COMPOUNDS and RADICLES.)

ponents. Thus, with regard to *colour:* yellow sulphur and grey mercury produce red cinnabar; purple iodine and grey potassium yield colourless iodide of potassium; purple iodine and grey lead form bright yellow iodide of lead; the colours of metallic oxides bear no relation whatever to those of the metals themselves, and the compounds of metals with chlorine, iodine, and other salt-radicles, are for the most part transparent, though the metals themselves are opaque. Again, we find organic compounds exhibiting an endless variety of colours, formed by the union of elements which in the free state have no colour at all. The *density* of a compound is very rarely an exact mean between that of its constituents, being generally higher and in a few cases lower; and the *taste, smell, refracting power, fusibility, volatility, conducting power for heat and electricity,* and other physical properties, are not for the most part such as would result from mere mixture of their components. It must not of course be understood that the physical properties of compounds are not related to those of their components by any regular laws. Definite relations doubtless exist, and will one day be discovered: indeed, the regular gradations of boiling point, atomic volume, &c., exhibited by the terms of homologous series of organic compounds, afford striking examples of them; still it is generally true that the properties of a definite compound are not intermediate between those of its components, as in a mixture or solution.

3. As to the *phenomena* which accompany the formation and decomposition of chemical compounds, especially as regards *temperature.* Chemical combination in definite proportions, is always attended with evolution of heat, sometimes amounting to vivid combustion, and decomposition is accompanied by absorption of heat and consequent reduction of temperature; whereas the mere mixing of liquids takes place without change of temperature, and the solution of a solid in a liquid, though partaking of the nature of combination, is attended with reduction of temperature, due to the passage of the body from the solid to the liquid state. So much is this the case, that a rise of temperature attending the contact of a solid and a liquid, may always be regarded as an indication of the formation of a definite compound; thus there are many anhydrous salts, such as chloride of calcium and sulphate of copper, which become strongly heated by contact with water, being at the same time converted into hydrates; but these hydrates, in subsequently dissolving in the water, produce a considerable degree of cold. (See HEAT.)

The formation and resolution of chemical compounds are also attended with changes in the *electrical state* of their elements. Whether the direct combination of two elements produces any electrical disturbance, is not perhaps clearly made out, on account of peculiar difficulties in the investigation of the phenomena (see ELECTRICITY); but the solution of a metal in an acid, which consists in the decomposition of one compound and the formation of another, calls into action a large amount of electric force, which by certain arrangements, hereafter to be considered, may be made to take the form of an electric current. Conversely, an electric current, no matter how developed, whether by chemical action, or by friction, or by magnetic induction, is capable of overcoming the most powerful chemical combinations, and causing the elements to travel through the circuit in opposite directions, and finally separate at the poles of the circuit. No such effect is, however, produced on mixtures or solutions. The passage of an electric current through the solution of a salt, resolves that salt into its elements, but never causes it to separate from the water as a whole.

For these reasons, we shall restrict the term CHEMICAL COMBINATION, to the formation of compounds in definite proportion, and AFFINITY, to the force which is concerned in their production, and proceed to consider more particularly the circumstances and results of chemical combination and decomposition.

Every elementary body is capable of uniting with others, and for the most part with every other. It is true that some of the compounds, as those of carbon with certain metals, of boron with silicon, selenium, and phosphorus, and of iodine with carbon, have either not been formed or are but imperfectly known; but there can be little doubt of the possibility of their formation. The compounds of fluorine with some of the other non-metallic elements are least known, on account of the difficulty of manipulating with fluorine in the free state.

Compounds resulting from the union of two simple substances, are called *binary compounds of the first order;* such are the metallic chlorides, oxides, and sulphides, the chlorides of hydrogen, sulphur, phosphorus, &c. Now, these compounds are capable of uniting with each other in various ways like elementary bodies, and hence result compounds containing three or four elements, which may be regarded as *binary compounds of the second order;* such are double chlorides, $KCl.PtCl^2$; oxygen-salts, as $Ba^2O.SO^3$; sulphur-salts $K^2S.As^2S^3$; hydrated chlorides $CaCl.3H^2O$, &c., and again these compounds of the second order may be conceived as uniting together to form *compounds of the third order*, such as double salts, *e. g.* common alum, which contains sulphate of potassium and sulphate of aluminium, $K^2O.SO^3 + Al^4O^3.3SO^3$. Further than this, the power of combination does not appear to extend.

This view of the successive building up of chemical compounds in binary groups, called the *Dualistic Theory* is, however, not the only one that can be taken, or indeed that which accords best with the present state of knowledge. It is for many reasons better to regard all compounds, whether containing two, three, or more elements, as constituted according to certain typical forms; for example, chlorides, iodides, bromides, and cyanides, as formed on the type of hydrochloric acid HCl; acids, bases, and salts containing oxygen or sulphur, seleniumn or tellurium, as formed on the type of water HH.O, &c. This is called the *Unitary Theory*. (See CLASSIFICATION, RADICLES, SUBSTITUTION, TYPES, and the various articles in which particular compounds are described.) It is true, indeed, that compounds containing three or more elements may, in many instances, be formed by the direct union of binary compounds of the first order; thus double chlorides and iodides are formed by fusing together the component simple chlorides, or by mixing their aqueous solutions and leaving them to crystallise; sulphur-salts, such as $Na^2S.As^2S^3$, by fusing together the simple sulphides; oxygen-salts also, in some instances, by heating together the so-called anhydrous acid and the base; thus boric anhydride and magnesia fused together in the proper proportion form borate of magnesium, $3Mg^2O.B^2O^3$ or Mg^3BO^3; and anhydrous baryta heated in vapour of sulphuric anhydride, burns and forms sulphate of barium, $Ba^2O.SO^3$ or Ba^2SO^4. But it by no means follows that the arrangement of the atoms in the resulting compound must be the same as in the simpler compounds from which it is formed; thus, while the mode of formation of sulphate of barium just mentioned would lead to the supposition that it is $Ba^2O.SO^3$, other modes of formation, and most of its reactions, indicate rather that its constitution is represented by the formula $Ba^2.SO^4$ or $SO^2.Ba^2.O^2$.

These observations apply chiefly to inorganic compounds. Organic bodies, with the exception of cyanogen and the hydrocarbons, all contain at least three elements, and the dualistic view of the building up of compounds by pairs cannot be applied to them at all, excepting on the supposition that they contain certain compound radicles, such as *ethyl*, C^2H^5, *benzoyl*, C^7H^5O, &c., which play the same part as metals in inorganic compounds, uniting like simple radicles, with oxygen, chlorine, bromine, &c. With the help of these radicles, some of which have been obtained in the free state, the constitution of the best known organic compounds, such as the alcohols, ethers, aldehydes, acetones, and their derivatives, may be assimilated to that of inorganic compounds, and represented either on the unitary or the dualistic view.

Formation and Decomposition of Chemical Compounds.

As chemical combination involves a total change in the arrangement of the atoms of the combining bodies, it is clear that cohesion, which tends to hold them in certain fixed positions, must be opposed to chemical union, and on the contrary, anything which gives mobility to the particles of the two bodies, and enables them to intermix and approach within small distances of each other, such as pulverisation, and more especially liquefaction, must tend to promote it.

a. Generally speaking, *one at least of the combining bodies must be either in the liquid or in the gaseous state*, and if it be not so at ordinary temperatures, it must be brought into that state by elevation of temperature. Solid bodies either do not combine at all, or their combination is attended with great difficulty, because, from the immobility of their particles, their points of immediate contact are but few, and the exceedingly thin film of compound which may be formed at such points, acts as a partition to prevent further contact and consequently further combination. But by continued rubbing, which renews the points of contact, more complete combination may often be effected: in this manner, finely divided copper may be made to combine with sulphur, the combination being even attended with rise of temperature. If, on the other hand, the compound formed by the two solids is itself fluid, its mobility gives rise to continually renewed contact, and combination goes on. Thus ice under 0° C. unites with chloride of sodium and other salts, and solid amalgam of lead with solid amalgam of bismuth. Crystallised oxalic acid and lime may be made to combine by rubbing them together, because the acid contains more water of crystallisation than the oxalate of calcium produced is able to take up: hence, at the beginning of the action, a little water is set free and dissolves the oxalic acid. In some cases it is sufficient to heat one of the solid bodies till it softens: thus iron surrounded with charcoal and heated to whiteness is slowly penetrated by the charcoal (*Cementation*). When, in consequence of one or both bodies being in the fluid state, combination takes place at the ordinary temperature or a little above it, it is called *solution in the wet way* (*Solutio via humida*): if a higher temperature is required, the process is called *solution in the dry way, fusion* (*Solutio via sicca, Confusio*).

b. Even if one or both of the bodies be in the fluid state, a higher temperature is often necessary to effect the combination.

Melted sulphur will not combine with carbon; the sulphur must be brought in the state of vapour into contact with red-hot charcoal, although the elasticity of the vapour might rather be expected to interfere with the combination. Neutral carbonate of of sodium, in the efflorescent state absorbs carbonic acid very slowly at first, but more and more quickly as it gets heated by the absorption, and ultimately with great violence. Charcoal requires to be heated before it will burn in oxygen gas, that is, before it will combine with the oxygen. At ordinary temperatures, oxygen may be mixed with hydrogen and other inflammable gases without combining with them, but at a red heat, combination takes place immediately. In this case both bodies are fluid, and we might expect that heat, by increasing their elasticity, would rather oppose than favour the combination. The manner in which heat acts in such cases is not precisely understood; but its effect is probably due to the increased rapidity of movement which it gives to the particles. (See HEAT.)

c. In some cases, *light* has the same effect as an elevation of temperature; thus chlorine, under the influence of light, unites directly with hydrogen or carbonic oxide.

d. *Electricity* likewise favours the combination of many substances, especially of gases, acting chiefly, perhaps, by elevation of temperature. In this manner the combination of oxygen with hydrogen, carbonic oxide or carburetted hydrogen, and of chlorine with hydrogen, is easily brought about.

e. In some instances, the *expansion of gaseous bodies* favours their combination with others. Phosphorus undergoes slow combustion in oxygen gas, however low the temperature may be, the action going on more quickly as the gas is more rarefied; a mixture of oxygen and non-inflammable phosphoretted hydrogen gases explodes on expansion.

f. The presence of a *solid body*, particularly a metal, having a great extent of surface, likewise causes, sometimes at ordinary, sometimes at slightly elevated temperatures, the combination of oxygen with inflammable gases and vapours, which would otherwise take place only at a red heat. This property is most strikingly exhibited by platinum; the more finely divided the platinum, the stronger is its action. When the combination of oxygen with inflammable gases take place at its surface, the heat developed raises its temperature and thereby increases its activity, till at length the metal becomes red-hot and then sudden combination occurs. Platinum appears to condense gases, particularly oxygen, on its surface, whereby the heterogenous atoms are made to approach one another and combine. A similar power is possessed by charcoal and other porous bodies (p. 761).

A body in the act of chemical combination often exhibits the power of inducing the same kind of activity in another body and causing it to combine with a third body, thereby forming a compound which, under the existing circumstances, would not have been formed without the presence of the first body (Liebig, Ann. Ch. Pharm. xxx. 262). Nitrogen gas does not by itself combine with oxygen, even when heated; but if a mixture of nitrogen and hydrogen be set on fire, the hydrogen burns, producing water, and a portion of the nitrogen combines at the same time with oxygen, producing nitric acid. Pure copper does not dissolve in dilute sulphuric acid, but when combined with zinc and nickel (in German silver), metals which decompose acidulated water, or when combined with three times its weight of zinc only, it dissolves completely together with the other metals. Platinum when alone does not dissolve in nitric acid, but when alloyed with silver it becomes soluble in that acid.

Chemical compounds may be formed, either by direct union of their elements, or by substitution of one element for another in a compound previously existing.

Oxygen unites directly with most other elements, either at ordinary or at elevated temperatures; so likewise do *sulphur*, *chlorine*, *iodine*, and *bromine*. *Hydrogen* unites directly with oxygen and chlorine at elevated temperatures, with the latter also at ordinary temperatures, under the influence of light; *nitrogen* shows but little tendency to unite directly with any other element; *phosphorus* unites readily with oxygen, chlorine, iodine, and bromine at ordinary temperatures; with sulphur and selenium with aid of a moderate heat. *Carbon*, at high temperatures, unites directly with oxygen, sulphur, and many metals, not with any other element. *Boron* and *silicium* combine directly with oxygen at ordinary temperatures, if they are in a state of minute division, more easily when heated; with other elements they exhibit little or no power of direct combination. *Metals* unite directly with oxygen, sulphur, selenium, chlorine, bromine, and iodine, sometimes at ordinary, sometimes at higher temperatures; in some instances also with phosphorus and with carbon. Alloys of definite constitution are also frequently produced by melting different metals together, though the greater number of such products are merely mixtures.

It has been already mentioned that compound bodies can unite with one another directly, forming new bodies of more complex constitution. These combinations are sometimes very energetic, as that of anhydrous baryta heated in the vapour of sulphuric anhydride, which is a true case of combustion.

Altogether, however, the cases in which compounds are formed by direct union of elements is small compared with that in which new compounds result from the transformation of others previously existing. Such transformations may be effected in various ways.

I. By *heat*, which may either expel one or more of the elements of the original compound in the free state, leaving the rest in a new form of combination, or may cause the whole of the elements to arrange themselves in the form of new compounds.—1. Chlorate of potassium, $KClO^3$, exposed to a full red heat, gives off the whole of its oxygen, and is converted into chloride of potassium, KCl. Similarly with other chlorates, also with bromates and iodates. Many metallic oxides and sulphides, when heated to redness, give off part of their oxygen or sulphur, and are reduced to lower oxides or sulphides.—2. Chlorate of potassium exposed to a degree of heat less than sufficient to expel the whole of the oxygen, is resolved into perchlorate and chloride of potassium: $3KClO^3 = KCl + 2KClO^4 + O$. Nitrate of ammonium, $NH^4.NO^3$, is resolved by heat into water, $2H^2O$, and nitrous oxide, N^2O. To this head likewise belong the numerous transformations of organic compounds, resulting from dry or destructive distillation.

II. By *electricity.*—The action of the electric current on chemical compounds, either in the fused state or in solution, gives rise to an endless variety of new products. In some instances, the elements of a compound are eliminated by electrolysis in the free state, as when water, hydrochloric acid, or certain metallic oxides, chlorides, or iodides are subjected to the action of the current; frequently, however, the elements arrange themselves in new combinations. We shall consider this subject more fully under ELECTRICITY; at present we will merely mention the formation of peroxide of lead at the positive pole, when a solution of nitrate or acetate of lead is electrolysed; the evolution of arsenetted hydrogen in the electrolysis of aqueous arsenious acid; and the decompositions of acetic acid and other fatty acids, into alcohol-radicles, hydrocarbons of the ethylene-series, carbonic anhydride, and hydrogen.

III. *By the action of another substance, simple or compound.*

a. The decomposing substance is an element (or a compound acting as such), and takes the place of one element of the compound, which is thereby eliminated. This is SIMPLE SUBSTITUTION.

Zinc decomposes hydrochloric acid, HCl, forming ZnCl, and expelling hydrogen. Potassium decomposes water, HHO, expelling half the hydrogen, and forming hydrate of potassium, KHO. Chlorine decomposes bromide of silver, forming chloride of silver and eliminating bromine. Metals in numerous instances displace other metals from solutions of their salts, *e. g.* iron decomposes nitrate of copper, forming nitrate of iron and a deposit of copper. Silicic anhydride, SiO^2, decomposes carbonate of soda, $Na^2O.CO^2$, expelling carbonic anhydride, and forming silicate of soda, $Na^2O.SiO^2$, though not exactly in the proportion here indicated. Boric anhydride, B^2O^3, heated with hydrate of barium expels 3 atoms of water, and forms borate of barium: $B^2O^3 + 3(H^2O.Ba^2O) = 3Ba^2O.B^2O^3 + 3H^2O$.

b. The acting body sometimes enters into combination with both elements of the compound, or with the compound as a whole.

Sulphide of carbon burnt in oxygen, produces sulphurous and carbonic anhydrides. Hydrocarbons and organic compounds in general, yield by combustion, carbonic anhydride and water. Chlorine converts metallic sulphides into chloride of sulphur and metallic chlorides. Chlorine passed into water forms hydrochloric and hypochlorous acids; it decomposes metallic oxides in like manner, forming with mercuric oxide, Hg^2O, for example, chloride of mercury, 2HgCl, and hypochlorous anhydride, Cl^2O. Sometimes only one compound is formed: as when a metallic sulphide is heated in the air and converted into a sulphate: *e. g.* $Cu^2S + O^4 = Cu^2SO^4$; or again, when phosphoretted hydrogen, PH^3, is converted by combustion into phosphoric acid, PH^3O^4.

c. The substance by which the compound AB is decomposed, is itself a compound CD, and the transformation consists in an interchange of elements, whereby the two new compounds AD and BC, are produced. This is DOUBLE DECOMPOSITION. It is the most frequent of all kinds of chemical action, and, as we shall presently explain, may be regarded as typical of the rest. Instances of it may be adduced without number, such as the mutual decomposition of neutral salts, *e. g.* chloride of barium and sulphate of copper; nitrate of silver and chloride of sodium, &c. Also the decomposition of metallic oxides by acids, resulting in the formation of chlorides, iodides, sulphides, &c. and oxygen-salts: thus, with hydrochloric acid and oxide of copper:

$$Cu^2O + H^2Cl^2 = Cu^2Cl^2 + H^2O;$$

hydrochloric acid and hydrate of potassium:

$$KHO + HCl = KCl + HHO;$$

sulphydric acid and oxide of lead:

$$H^2S + Pb^2O = H^2O + Pb^2S.$$

Sulphuric acid and protoxide of iron:

$$H^2SO^4 + Fe^2O = Fe^2SO^4 + H^2O;$$

sulphuric acid and sesquioxide of iron:

$$3H^2SO^4 + Fe^4O^3 = Fe^4(SO^4)^3 + 3H^2O.$$

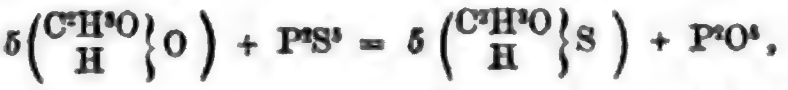
Similarly when compound radicles are concerned, as in organic compounds: *e.g.* the formation of water and chloride of ethyl by the mutual action of alcohol and hydrochloric acid:

$$\left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O + HCl = C^2H^5Cl + H^2O;$$

of ethylsulphuric acid and water, from alcohol and sulphuric acid:

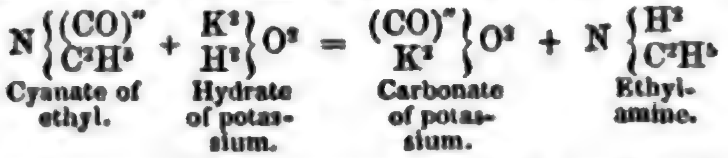
$$\left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O + \left.\begin{matrix}H\\H\end{matrix}\right\}SO^4 = \left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}SO^4 + \left.\begin{matrix}H\\H\end{matrix}\right\}O;$$

of thiacetic acid and phosphoric anhydride, from acetic acid and pentasulphide of phosphorus:



$$5\left(\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O\right) + P^2S^5 = 5\left(\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}S\right) + P^2O^5,$$

of ethylamine by the action of hydrate of potassium on cyanate of ethyl:



$$\underset{\text{Cyanate of ethyl.}}{N\left\{\begin{matrix}(CO)''\\C^2H^5\end{matrix}\right.} + \underset{\text{Hydrate of potassium.}}{\left.\begin{matrix}K^2\\H^2\end{matrix}\right\}O^2} = \underset{\text{Carbonate of potassium.}}{\left.\begin{matrix}(CO)''\\K^2\end{matrix}\right\}O^2} + \underset{\text{Ethylamine.}}{N\left\{\begin{matrix}H^2\\C^2H^5\end{matrix}\right.}$$

In some cases, the decomposition of a compound, AB, is effected by the joint action of two substances C, D, not previously combined; as when an oxide, alumina, for example, is decomposed by the joint action of chlorine and carbon at a red heat, yielding a chloride and carbonic oxide:

$$Al^4O^3 + Cl^6 + C^3 = 2Al^2Cl^3 + 3CO.$$

Sometimes, instead of the two new compounds AD, BC, being produced, only one such compound, AD, is formed, the elements B C being either set free or entering into other combinations. Thus when chloride of ammonium is decomposed by quick lime, the products should be chloride of calcium and oxide of ammonium; but the latter is immediately resolved into ammonia and water:

$$2NH^4Cl + Ca^2O = 2CaCl + (NH^4)^2O\ [= 2NH^3 + H^2O].$$

Aluminium and other sesquiatomic metals do not form carbonates: hence, when a salt of aluminium is precipitated by an alkaline carbonate, the precipitate consists, not of carbonate of aluminium, but of alumina (hydrated), while carbonic anhydride is set free:

$$2Al^2Cl^3 + 3Na^2CO^3 = 6NaCl + Al^4O^3 + 3CO^2.$$

Many peroxides heated with hydrochloric acid, yield water, a protochloride of the metal, and free chlorine, the metal not forming a chloride analogous in composition to the peroxide:

$$MnO + 2HCl = H^2O + MnCl + Cl$$

In many cases, one or both of the new products, AD, BC, enters into combination with an undecomposed portion of one or both of the original compounds, the particular products formed depending upon the proportion in which the original substances are present, and on the circumstances of the experiment. Thus, when sulphide of carbon is decomposed by potash, the immediate products are sulphide of potassium and carbonic anhydride; but these unite with portions of the original substances, forming carbonate and sulphocarbonate of potassium:

$$3CS^2 + 3K^2O = K^2O.CO^2 + 2(K^2S.CS^2).$$

Sulphide of antimony fused with potash, yields at first sulphide of potassium and oxide of antimony; but the final products are oxysulphide of antimony and sulphantimonite of potassium:

$$3Sb^2S^3 + 3K^2O = Sb^2O^3.Sb^2S^3 + 3K^2S.Sb^2S^3;$$

but when 4 at. trisulphide of antimony are fused with 7 at. potash, the products are 2 at. sulphantimonite and 1 at. acid antimonite of potassium:

$$4Sb^2S^3 + 7K^2O = 2(3K^2S.Sb^2S^3) + K^2O.2Sb^2O^3.$$

It has already been stated that double decomposition may be viewed as a type of chemical action in general; in fact, all cases of simple substitution, and even of the direct union of two elements, or the separation of the elements of a binary compound, may be viewed as double decompositions, provided we make certain suppositions respecting the constitution of elements in the free state.

There are many considerations which tend to show that the atoms of an elementary body, or of a compound radicle in the free state, are associated by pairs in a similar manner to the heterogenous atoms of a binary compound; that is to say, a molecule of free hydrogen consists of HH, and a molecule of free ethyl of $C^2H^5.C^2H^5$, just as a molecule of hydrochloric acid consists of HCl, and a molecule of chloride of ethyl of $C^2H^5.Cl$. In the voltaic circuit, the metallic conductor exhibits in many respects the same phenomena as the electrolyte, both parts of the circuit becoming heated, and both producing the same deflection of a magnetic needle placed near them: hence it may be inferred, that the metallic conductor consists of a series of similar particles polarised in pairs, just as the electrolyte consists of a series of heterogeneous particles thus polarised. In a circuit composed of zinc, platinum, and hydrochloric acid, the electrolyte may be regarded as consisting of $\overset{-}{\mathrm{Cl}}\overset{+}{\mathrm{H}}\quad\overset{-}{\mathrm{Cl}}\overset{+}{\mathrm{H}}\quad\overset{-}{\mathrm{Cl}}\overset{+}{\mathrm{H}}$ . . . and the metallic part of the circuit of $\overset{-}{\mathrm{Zn}}\overset{+}{\mathrm{Zn}}\quad\overset{-}{\mathrm{Zn}}\overset{+}{\mathrm{Zn}}\quad\overset{-}{\mathrm{Zn}}\overset{+}{\mathrm{Zn}}$ . . . $\overset{-}{\mathrm{Pt}}\overset{+}{\mathrm{Pt}}\quad\overset{-}{\mathrm{Pt}}\overset{+}{\mathrm{Pt}}$ . . . the entire circuit being thus made up of atoms in opposite polar states. This, as will be more fully explained in the article ELECTRICITY, is the most satisfactory idea that can be given of the phenomena of electro-chemical action.

But there are also considerations purely chemical which tend to the same conclusion. Many instances of chemical action are known, in which two atoms of an elementary body or compound radicle unite together at the moment of chemical change, just like heterogeneous atoms.

Thus, when hydride of copper, Cu^2H, is decomposed by hydrochloric acid, cuprous chloride is formed, and a quantity of hydrogen evolved, equal to twice that which is contained in the hydride itself:

$$Cu^2H + HCl = Cu^2Cl + HH.$$

This action is precisely analogous to that of hydrochloric acid on cuprous oxide:

$$Cu^4O + 2HCl = 2Cu^2Cl + H^2O.$$

In the latter case, the hydrogen separated from the hydrochloric acid unites with oxygen; in the former, with hydrogen. When solutions of sulphurous and sulphydric acids are mixed, the whole of the sulphur is precipitated:

$$SO^2 + 2H^2S = 2H^2O + S.S^2,$$

the action being similar to that of sulphurous acid on selenhydric acid:

$$SO^2 + 2H^2Se = 2H^2O + S.Se^2.$$

In the one case, a sulphide of selenium is formed; in the other, a sulphide of sulphur. The precipitation of iodine, which takes place on mixing hydriodic with iodic acid, affords a similar instance of the combination of homogenous atoms. The reduction of certain metallic oxides by peroxide of hydrogen, is another striking example of this kind of action. When oxide of silver is thrown into this liquid, water is formed; the silver is reduced to the metallic state; and a quantity of oxygen is evolved, equal to twice that which is contained in the oxide of silver. It appears, indeed, as if atoms could not exist in a state of isolation. An atom of an elementary body must unite, either with an atom of another element, or with one of its own kind.

Similar phenomena are exhibited by the alcohol-radicles: thus, when zinc-ethyl and iodide of methyl are heated together, double decomposition takes place, the products being iodide of zinc and methyl-ethyl:

$$C^2H^5.Zn + CH^3.I = ZnI + CH^3.C^2H^5;$$

and when zinc-ethyl is heated with iodide of ethyl, a precisely similar action takes place, but attended with formation of free ethyl:

$$C^2H^5.Zn + C^2H^5.I = ZnI + C^2H^5.C^2H^5.$$

In the first case, the ethyl separated from the iodine unites with methyl separated from the zinc; in the second, it unites with another atom of ethyl. The idea of the duality of the molecules of alcohol-radicles in the free state, is likewise in accordance with their observed boiling-points and vapour-densities. (See ALCOHOL-RADICLES, p. 96.)

Further, elementary bodies frequently act upon others as if their atoms were associated in binary groups. Thus chlorine acting upon potash forms two compounds, chloride and hypochlorite of potassium:

$$KKO + ClCl = ClK + ClKO;$$

just as chloride of cyanogen would form chloride and cyanate of potassium. The quantity of chlorine which acts upon an atom of potash, is not 1 at. = 35·5, but 2 at. = 70. Similarly, when metallic sulphides oxidise in the air, both the metal and the sulphur enter into combination with oxygen. Sulphur acting upon potash forms a sulphide and a hyposulphite. Lastly, when zinc-ethyl is exposed to the action of chlorine, iodine, &c., these elements unite separately with the zinc and with the ethyl, thus:

$$C^2H^5Zn + ClCl = C^2H^5Cl + ZnCl.$$

From these considerations it appears that double decomposition, which is generally understood as an action between four elements or groups of elements, may likewise be supposed to take place in cases where only three elements or groups come into play. In like manner we may regard as double decompositions even those reactions which are commonly viewed as the simple combination or separation of two elements, or as the substitution of one element for another. Thus when potassium burns in chlorine gas, the reaction may be supposed to take place between two atoms of chlorine and two atoms of potassium:

$$KK + ClCl = KCl + KCl.$$

Again, the decomposition of cyanide of mercury by heat may be represented thus:

$$CyHg.CyHg = CyCy + HgHg.$$

The simple replacement of one element by another may also be regarded as a double decomposition, by supposing the formation of an intermediate compound. Thus the action of zinc upon hydrochloric acid may be supposed to consist of two stages:

$$ZnZn + HCl = ZnH + ZnCl,$$

and

$$ZnH + HCl = ZnCl + HH.$$

It is true that the formation of the intermediate compound, the hydride of zinc, cannot be actually demonstrated in this case, because it is decomposed as fast as it is formed; but in other cases, the two stages of the action can be distinctly traced. Thus, it is well known that hydrochloric acid does not dissolve copper; but an alloy of zinc and copper, Cu^2Zn, dissolves in it readily, with evolution of hydrogen. Here it may be supposed that the first products are chloride of zinc and hydride of copper, a known compound:

$$Cu^2Zn + HCl = Cu^2H + ZnCl;$$

and that the hydride is afterwards acted upon by the acid in the manner already explained. Again, when zinc and iodide of ethyl are heated together in a sealed tube, iodide of zinc and zinc-ethyl are obtained, thus:

$$ZnZn + (C^2H^5).I = ZnI + Zn(C^2H^5);$$

and the zinc-ethyl, when heated with excess of iodide of ethyl, yields iodide of zinc and free ethyl (p. 857).

It thus appears that all well understood cases of chemical action may be referred to one type, namely, that of an interchange of elements between two previously existing compounds.

d. The transformation of a compound is brought about by a substance which either remains unaltered, or at all events does not enter into combination with either of the elements of the compound. This obscure mode of action, usually called *Catalysis*, or *Contact-action*, is chiefly observed in the transformations of organic compounds, such as the conversion of sugar into alcohol and carbonic acid, and of alcohol into acetic acid under the influence of yeast; of starch into dextrin and sugar by the action of diastase; the conversion of urea into carbonate of ammonium, by contact with animal mucus, &c. The terms Catalysis and Contact-action explain nothing, but as mere names they are sometimes convenient. Many decompositions formerly spoken of as catalytic, are now regarded as double decompositions, dependent on the polarity of homogeneous atoms (p. 837).

Magnitude or Strength of Chemical Affinity.

That the power which causes bodies to unite is exerted with various degrees of intensity, is evident from the whole range of chemical phenomena. Chlorine certainly unites with hydrogen more readily than with nitrogen, and the elements of hydrochloric acid are held together with far greater force than those of chloride of nitrogen. If zinc displaces copper from its solution in hydrochloric acid, and copper cannot displace zinc from such a solution, we cannot resist the conclusion that the affinity of zinc for chlorine in solution is greater than that of copper. But does this show that the former of these affinities is intrinsically and under all circumstances greater than the latter? or may not the relative solubilities of chloride of zinc and chloride of copper, or the cohesion of the metals themselves, have something to do with the result? Or to state the question generally, does each element possess for every other a distinct and specific affinity or combining power, which is always the same, and liable only to be modified in its results by the circumstances under which the bodies are placed,—or is the affinity between each pair of elements itself a variable quantity dependent on pressure, temperature, solubility, volatility, the presence of other bodies, &c. &c.? The older chemists answered the first part of this question in the affirmative. When they found a body A expelling another B from its union with C, they concluded that C had for A a greater affinity than for B.

On this principle they formed what were called *Tables* or *Columns of Affinity*, of which the following may be taken as specimens, the several substances in each being disposed in the order of their supposed affinity for the body at the head of the column:

Sulphur: O; K and the other alkali-metals; Zn; Fe; Sn; Cu; Cl; H; C; Pb; Bi; Sb; Hg; Ag; Pt; Cu^4S; MoS; Au.

Sulphuric acid: Ba^2O; Sr^2O; K^2O; Na^2O; Li^2O (?); Ca^2O; Mg^2O; Pb^2O; NH^3; Fe^2O; Zn^2O; Ni^2O: Co^2O; Cu^2O; Al^4O^3; Fe^4O^3.

Metals: O; F; Cl; Br; I; Se; P; H.

A very slight acquaintance with chemical phenomena is, however, sufficient to show that these so-called Tables of Affinity are merely tables of the order of decomposition under particular circumstances, and that the relative affinity of one body for two others is liable to change from a great variety of circumstances, sometimes even to be reversed. Thus, iron at a red heat decomposes vapour of water, abstracting the oxygen and setting the hydrogen free, whence it might be inferred that the affinity of oxygen for iron is greater than for hydrogen; but if hydrogen gas be passed over red-hot oxide of iron, water is formed and iron set free, indicating an exactly opposite order of affinities. In like manner, potassium heated in an atmosphere of carbonic anhydride, becomes oxidised and sets carbon free; and on the other hand, charcoal strongly heated with potash, abstracts the oxygen and sets potassium free. Carbonic anhydride precipitates silica from a solution of silicate of sodium, and on the other hand silica heated with carbonate of sodium, forms silicate of sodium, and liberates carbonic anhydride; and similarly in numerous other cases.

We must then look to other circumstances besides intrinsic force of affinity to determine whether a particular reaction will take place or not. The most important of these circumstances are:

1. The *elasticity* or the *cohesion* of one of the resulting compounds, and its consequent tendency to assume the gaseous or solid state, and thus to remove itself from the sphere of action.

The examples just mentioned afford striking illustrations of the influence of volatility in determining chemical decomposition. The tendency of the resulting gas or vapour to diffuse itself through the surrounding atmosphere, doubtless contributes greatly to the result; thus, when aqueous vapour is passed over red-hot iron, the hydrogen set free by the decomposition of the water is carried forward by the current of aqueous vapour, and the iron is left free to act upon a fresh portion. The influence of cohesion is clearly seen in precipitations. It is, indeed, a general law that if the solutions of two salts are mixed, and an insoluble compound can be formed from any of their elements, that compound is sure to be produced and to separate from the liquid. Hence the order of decomposition is frequently reversed by the nature of the solvent. Aqueous acetic acid decomposes carbonate of potassium, eliminating carbonic acid; but if the resulting acetate of potassium be dissolved in alcohol, and carbonic acid gas passed through the solution, carbonate of potassium is precipitated and acetic acid passes into solution as acetic ether. A strong solution of caustic potash decomposes carbonate of calcium, forming carbonate of potassium, and leaving lime undissolved; but a solution of 1 pt. carbonate of potassium in 10 pts. of water, is decomposed by agitation with lime, yielding caustic potash and carbonate of calcium. A weak solution of sulphurous acid dissolves iodine, forming hydriodic and sulphuric acids, $H^2SO^3 + I^2 + H^2O = 2HI + H^2SO^4$; but if the quantity of water in the solution be diminished by evaporation, sulphurous anhydride is evolved and hydriodic acid containing iodine remains behind, $H^2SO^4 + 2HI = I^2 + SO^2 + 2H^2O$.

2. *The relative quantities of the acting substances.*—That the relative degrees of affinity of a body for a number of others to which it is simultaneously presented are greatly modified by their relative masses, was first pointed out by Berthollet. The law laid down by that philosopher respecting the action of masses, is this:—*A body to which two different substances capable of acting on it chemically, are presented in different proportions, divides itself between them in the ratio of the products of their*

respective masses, and the absolute strengths of their affinities for the first body. Thus, if we denote by A and B the masses of the two bodies which are present in excess, by α and β the coefficients of their absolute affinities for the body C; and by a and b the quantities of A and B which actually combine with C, the law just stated will be expressed by the proportion:

$$a : b = \alpha A : \beta B.$$

If this view be correct, any alteration, however small, in the relative quantities of A and B, must produce a corresponding alteration in the relative quantities of the two which unite with C. That this is not the case under all circumstances, is shown by the following experiments of Bunsen and of Debus.

Bunsen's experiments (Ann. Ch. Pharm. lxxxv. 137), which were made in such a manner that all the phenomena of combination concerned in them took place simultaneously, lead to the following remarkable laws:

1. When two or more bodies, BB' . . . are presented in excess to the body A, under circumstances favourable to their combination with it, the body A always selects of the bodies BB' . . . quantities which stand to one another in a simple atomic relation, so that for 1, 2, 3 . . . atoms of the one compound, there are always formed 1, 2, 3 . . . atoms of the other; and if in this manner there is formed an atom of the compound AB', in conjunction with an atom of AB, the mass of the body B may be increased relatively to that of B', up to a certain limit, without producing any alteration in the atomic proportion.

When carbonic oxide and hydrogen are exploded with a quantity of oxygen not sufficient to burn them completely, the oxygen divides itself between the two gases in such a manner that the quantities of carbonic anhydride and water produced stand to one another in a simple atomic proportion. The results of Bunsen's experiments are given in the following table, the numbers in which denote volumes:

Composition of Gaseous Mixture.			Quantities of CO and H consumed by Detonation.		Ratio of CO : H.
72·57 CO	. 18·29 H	. 9·14 O	12·18 CO	. 6·10 H	2 : 1
59·93 „	. 26·71 „	. 13·36 „	13·06 „	. 13·66 „	1 : 1
36·70 „	. 42·17 „	. 21·13 „	10·79 „	. 31·47 „	1 : 3
40·12 „	. 47·15 „	. 12·73 „	4·97 „	. 20·49 „	1 : 4

The results were the same whether the explosion took place in the dark, in diffused daylight, or in sunshine; and were not affected by the pressure to which the gaseous mixture was subjected.

The proportions of hydrogen and carbonic oxide consumed in these several experiments, correspond with the composition of five hydrates of carbonic anhydride, containing, respectively:

$$H^2O.2CO^2;\ H^2O.CO^2;\ 2H^2O.CO^2;\ 3H^2O.CO^2;\ 4H^2O.CO^2;$$

but the results cannot be attributed to the actual formation of these hydrates, inasmuch as hydrates of acids containing several atoms of water are incapable of existing at high temperatures.

2. *When a body, A, exerts a reducing action on a compound, BC, present in excess, so that A and B combine together and C is set free; then, if C can, in its turn, exert a reducing action on the newly-formed compound, AB, the final result of the action is, that the reduced portion of BC is to the unreduced portion in a simple atomic proportion.*

In this case, also, the mass of the one constituent may, without altering the existing atomic relation, be increased to a certain limit, above which, that relation undergoes changes by definite steps, but always in the proportion of simple rational numbers.

When vapour of water is passed over red-hot charcoal, the carbon is oxidised and hydrogen is separated; but the process does not go on so far as the complete formation of carbonic anhydride, but stops at the point at which 1 vol. carbonic anhydride and 2 vol. carbonic oxide are formed to every 4 vol. of hydrogen.

In the imperfect combustion of cyanogen—the gaseous mixture being so far diluted that it will but just explode, in order that the temperature may not rise too high, and the result be consequently vitiated by the partial oxidation of the nitrogen — carbonic anhydride and carbonic oxide are formed, and nitrogen set free, likewise in simple atomic proportion. A mixture of 18·05 vol. cyanogen, 28·87 oxygen, and 53·08 nitrogen, gave, by detonation, 2 vol. carbonic oxide, and 4 vol. carbonic anhydride to 3 vol. nitrogen.

In the combustion of a mixture of carbonic anhydride, hydrogen, and oxygen, in which the carbonic anhydride is exposed at the same time to the reducing action of the hydrogen and the oxidising action of the oxygen, the reduced portion of the carbonic anhydride is likewise found to bear to the unreduced portion a simple atomic relation. In the combustion of a mixture of 8·52 carbonic anhydride, 70·33 hydrogen, and 21·15 oxygen, the resulting carbonic oxide was to the reduced carbonic anhydride in the ratio of 3 : 2. After the combustion of a mixture of 4·41 vol. carbonic oxide, 2·96 carbonic anhydride, 68·37 hydrogen, and 24·26 oxygen, the volume of the carbonic oxide converted into carbonic anhydride by oxidation, was to that of the residual carbonic oxide as 1 : 3.

That these remarkable laws had not been previously observed, is attributed by Bunsen to the fact that they hold good only when the phenomena of combination, which are regulated by them, take place simultaneously: for, even if a body *A* were originally to select for combination from the bodies *B* and *C*, quantities bearing to one another a simple atomic relation, but the combination of *A* and *B* were to take place in a shorter time than that of *A* and *C*, it would follow of necessity, that during the whole of the process, the ratio of *B* to *C*, and therefore, also the atomic relations of the associated compounds, would change, so that the observed proportion would be no longer definite. The same result must follow if the bodies which are combining side by side are not homogeneously mixed in the beginning.

With regard to the bearing of these results on Berthollet's law, it might be objected that, in some of the experiments, as in the combustion of a mixture of carbonic oxide, hydrogen, and oxygen, one of the products, viz. the water, is removed from the sphere of action by condensation, and that the circumstances are therefore similar to the removal of an insoluble product by precipitation. It is scarcely conceivable, however, that a reverse action would take place, even if the gaseous mixture were to remain at the temperature which exists during the combustion. Moreover, in the decomposition of vapour of water by red-hot charcoal, the whole of the products remain in the gaseous state.

Debus (Ann. Ch. Pharm. lxxvx. 103; lxxxvi. 156; lxxxvii. 238), has obtained results similar to those of Bunsen, by precipitating mixtures of lime and baryta-water with aqueous carbonic acid, or mixtures of chloride of barium and chloride of calcium with carbonate of sodium. A small quantity of a very dilute solution of carbonate of sodium added to a liquid containing 5 pts. of chloride of barium to 1 pt. of chloride of calcium, threw down nearly pure carbonate of calcium; but when the proportion of the chloride of barium in the mixture was 5·7 times as great as that of the chloride of calcium, 2·3 pts. of the former were decomposed to 1 pt. of the latter. Hence it appears that, in this reaction also, limits exist at which the ratio of the affinities undergoes a sudden change. In these experiments, however, the products are immediately removed from the sphere of action, and the results are therefore not comparable with those which are obtained when all the substances present remain mixed and free to act upon each other.

The latter condition is most completely fulfilled in the mutual actions of liquid compounds, such as solutions of salts, when all the possible products of their mutual actions are likewise soluble; as, for example, when nitrate of sodium in solution is mixed with sulphate of copper. The question to be solved in such cases is this. Suppose two salts AB, CD, the elements of which can form only soluble products by their mutual interchange, to be mixed together in solution. Will these elements, according to their relative affinities, either remain in their original state of combination, as AB and CD, or pass completely into the new arrangement AD and CB?—or will each of the two acids divide itself between each of the two bases, producing the four compounds AB, AD, BC, BD? and, if so, in what manner will the relative quantities of these four compounds be affected by the original quantities of the two salts? Do the amounts of AD and CB, produced by the reaction, increase progressively with the regular increase of AB, as required by Berthollet's theory? or do sudden transitions occur, like those observed in the experiments of Bunsen and Debus?

The solution of this question is attended with considerable difficulty. For when two salts in solution are mixed, and nothing separates out, it is by no means easy to ascertain what changes may have taken place in the liquid. The ordinary methods of ascertaining the composition of the mixture, such as concentration, or precipitation by reagents, are inadmissible, because any such treatment immediately alters the mutual relation of the substances present. In some cases, however, the mixture of two salts is attended with a decided change of colour, without any separation of either of the constituents, and such alterations of colour may afford indications of the changes which take place in the arrangement of the molecules. This method has been employed by Dr. Gladstone (Phil. Trans. 1855, 179; Chem. Soc. Qu. J. ix. 54), who has carefully examined the changes of colour attending the mixture of a great variety of salts, and applied the results to the determination of the effect of mass in influencing chemical action.

Dr. Gladstone's principal experiments were made with the blood-red sulphocyanate of iron, which is formed on adding sulphocyanic acid or any soluble sulphocyanate to a solution of a ferric salt. On mixing known quantities of different ferric salts with known quantities of different sulphocyanates, it was found that the iron was never completely converted into the red salt; that the amount of it so converted depended on the nature both of the acid combined with the ferric oxide, and of the base combined with the sulphocyanogen; and that it mattered not how the bases and acids had been combined previous to their mixture, so long as the same quantities were brought together in solution. The effect of mass was tried by mixing equivalent proportions of ferric salts and sulphocyanates, and then adding known amounts of one or the other compound. It was found that, in either case, the amount of the red salt was increased, and in a regular progression according to the quantity added. When sulphocyanate of potassium was mixed in various proportions with ferric nitrate, chloride, or sulphate, the rate of variation appeared to be the same, but with hydrosulphocyanic acid it was different. The deepest colour was produced when ferric nitrate was mixed with sulphocyanate of potassium; but even on mixing 1 at. of the former with 3 at. of the latter, only 0·194 at. of the red sulphocyanate of iron was formed; and even when 375 at. of sulphocyanate of potassium had been added, there was still a recognisable amount of ferric nitrate undecomposed. The results of a series of experiments with ferric nitrate and sulphocyanate of potassium are given in the following table:

Ferric Nitrate.	Sulphocyanate of Potassium.	Red Salt produced.	Ferric Nitrate.	Sulphocyanate of Potassium.	Red Salt produced.
1 equiv.	3 atoms.	88	1 atom.	63 atoms.	356

1 ,,	28·2 ,,	266	1 ,,	375 ,,	587
1 ,,	46·2 ,,	318			

The addition of a colourless salt reduced the colour of a solution of ferric sulphocyanate, the reduction increasing in a regularly progressive ratio, according to the mass of the colourless salt.

Similar results were obtained with other ferric salts, viz. with the black gallate, the red meconate and pyromeconate, the blue solution of Prussian blue in oxalic acid, &c., and likewise with the coloured salts of other metals, *e. g.* the scarlet bromide of gold, the red iodide of platinum, the blue sulphate of copper, when treated with different chlorides, &c.

The amount of fluorescence exhibited by a solution of acid sulphate of quinine was found to be affected by the mixture of a chloride, bromide, or iodide, according to the nature and mass of the salt added; and the addition of sulphuric, phosphoric, nitric, and other acids was found to produce a fluorescence in solutions of hydrochlorate of quinine, or of sulphate which had been rendered non-fluorescent by the addition of hydrochloric acid. Solutions of horse-chestnut bark, and of tincture of thorn-apple, yielded similar results.

The conclusions to be drawn from Gladstone's experiments, are as follows:

When two or more binary compounds are mixed under such circumstances that all the resulting compounds are free to act and react, each acid element enters into combination with each basylous element in certain constant proportions, which are independent of the manner in which the different elements are primarily arranged, and are not merely the resultant of the various strengths of affinity of the several substances for each other, but are dependent also on the mass of each of the substances present in the mixture. All deductions respecting the arrangement of substances in solution, drawn from such empirical rules as that the strongest acid combines with the strongest base, must therefore be looked upon as doubtful. An alteration in the mass of any of the binary compounds present, alters the amount of every one of the other binary compounds, and that in a regularly progressive ratio, sudden transitions occurring only where a substance is present, which is capable of combining with another in more than one proportion. This equilibrium of affinities arranges itself in most cases in an inappreciably short time; but, in certain instances, the elements do not attain their final state of combination for hours.

Totally different phenomena present themselves where precipitation, volatilisation, crystallisation, and perhaps other actions occur, simply because one of the substances is thus removed from the field of action, and the equilibrium, which was at first established, is thus destroyed.

The reciprocal action of salts in solution has also been examined by Malaguti (Ann. Ch. Phys. [3] xxxvii. 198; and by Margueritte (Compt. rend. xxxviii. 305), both of whom conclude that each base divides itself between the several acids. Malaguti concludes from his experiments that, in the mutual action of two salts, if nothing separates from the liquid, the decomposition is most complete when the strongest acid and the strongest base are not originally united in the same salt, and that two experiments of this kind, made in opposite ways, must lead to the same final result; that, for example, when 1 at. of acetate of barium is added to 1 at. of nitrate of lead, the quantities of nitrate of barium and nitrate of lead ultimately present in the liquid are the same as when 1 at. nitrate of barium is mixed with 1 at. acetate of lead.

Margueritte finds that two salts in solution decompose each other, even when one of them is already the least soluble of the four salts that may be produced from the acids and bases present. Thus, a saturated solution of chlorate of potassium to which chloride of sodium is added, becomes capable of dissolving an additional quantity of chlorate of potassium, showing that a portion of the chlorate has been decomposed and a more soluble salt formed.

There are, however, certain well known phenomena, which show that this distribution of acids and bases in solution does not always take place. Boric acid colours litmus wine-red; sulphuric acid turns it bright red. Now if sulphuric acid be gradually added to a warm solution of borate of sodium in water which has been coloured blue with litmus, the liquid at first remains blue, because a combination of soda with excess of boric acid is produced; on the addition of more sulphuric acid, boric acid is set free, and colours the liquid wine-red; and not till all the soda has entered into combination with the sulphuric acid does a further addition of that acid give the liquid a bright red colour; but if sulphuric acid were present at the commencement of the action, either in the free state or combined with sulphate of sodium in the form of an acid salt, the bright red colour would appear at once. From the same cause, a solution of sulphate of potassium or sodium to which boric acid has been added, colours litmus only wine-red; but the addition of $\frac{1}{5000}$ of sulphuric acid immediately produces the bright red tint. Hence boric acid does not take soda from sulphuric acid or set that acid free.—Sulphydric acid and carbonic acid exhibit similar relations towards sulphuric acid.—Tincture of litmus is instantly bleached by chlorine-water, but not till after several days by aqueous solution of iodine: now, a solution of chloride of sodium mixed with iodine should, according to Berthollet, produce a mixture containing chloride of sodium with excess of chlorine, and iodide of sodium with excess of iodine. But the orange-yellow mixture colours litmus green (from the yellow of the solution and the blue of the tincture): and a very small quantity of chlorine-water immediately changes this green colour into the orange-yellow of the solution of iodine: this shows that no chlorine had been set free by the iodine.—Ferric phosphate is soluble in hydrochloric acid, but not in acetic acid. From its solution in hydrochloric acid it is completely precipitated by acetate of potassium. Now if the potash had been divided between the hydrochloric and acetic acids, part of the hydrochloric acid would have remained free, and would have held some of the phosphate of iron in solution. (Gm. i. 153.)

The decomposition of soluble by insoluble salts, affords a striking instance of the tendency of atoms to interchange, and of the influence of mass on chemical action. According to H. Rose (Pogg. Ann. xciv. 481; xcv. 96, 284), sulphate of barium is completely decomposed by boiling with solutions of alkaline carbonates, provided that each atom of sulphate of barium is acted upon by at least 15 at. of the alkaline carbonate. When 1 at. of sulphate of barium is boiled with only 1 at. of carbonate of potassium, only $\frac{1}{5}$ of it is decomposed, and only $\frac{1}{11}$ by boiling with 1 at. of carbonate of sodium, further decomposition being prevented by the presence of the alkaline sulphate already formed. If, however, the liquid be decanted after a while, the residue boiled with a fresh portion of the alkaline carbonate, and these operations repeated several times, complete decomposition is effected. Carbonate of barium is converted into sulphate by the action of an aqueous solution of sulphate of potassium or sodium, even at ordinary temperatures. Solution of carbonate of ammonium does not decompose sulphate of barium either at ordinary or at higher temperatures; carbonate of barium is not decomposed by sulphate of ammonium at ordinary temperatures, but easily on boiling. Sulphate of barium is not decomposed by boiling with caustic potash-solution, provided the carbonic acid of the air be excluded; but by fusion with hydrate of potassium it is decomposed, with formation of carbonate of barium, because the carbonic acid of the air cannot then be completely excluded. Hydrochloric and nitric acids, left in contact at ordinary temperatures with sulphate of barium, either crystallised or precipitated, dissolve only traces of it; at the boiling heat, a somewhat larger quantity is dissolved, and the solution forms a cloud, both with a dilute solution of chloride of barium and with dilute sulphuric acid. Sulphate of strontium is dissolved by hydrochloric acid at ordinary temperatures, sufficiently to form a slight precipitate with dilute sulphuric acid, and with chloride of strontium. Sulphate of calcium treated with hydrochloric acid, either cold or boiling, yields a liquid in which a precipitate is formed, after a while, by dilute sulphuric acid, but not by chloride of calcium.

Sulphate of strontium and sulphate of calcium are completely decomposed by solutions of the neutral and acid carbonates of the alkali-metals at ordinary temperatures, and more quickly on boiling, even if considerable quantities of an alkaline sulphate are added to the solution: the decomposition is also effected by carbonate of ammonia, even at ordinary temperatures. The carbonates of strontium and calcium are not decomposed by solutions of the sulphates of potassium or sodium at any temperature; sulphate of ammonium does not decompose them at ordinary temperatures, but readily with the aid of heat.

Sulphate of lead is completely converted into carbonate by solutions of the neutral and acid carbonates of the alkali-metals, even at ordinary temperatures, the neutral carbonates, but not the acid carbonates, then dissolving small quantities of oxide of lead. Carbonate of lead is not decomposed by solutions of the alkaline sulphates, either at ordinary temperatures or on boiling.

Chromate of barium is decomposed at ordinary temperatures by solutions of the neutral carbonates of the alkali-metals, and much more easily by boiling with excess of an acid carbonate of alkali-metal. When equivalent quantities of the chromate of barium and carbonate of sodium are boiled with water, $\frac{1}{7}$ of the whole is decomposed; when the same quantities of the salts are fused together, and the mass treated with water, only $\frac{1}{87}$ of the barium-salt is decomposed. Carbonate of barium is completely converted into chromate by digestion with the solution of an alkaline monochromate; and the decomposition of chromate of barium by neutral alkaline carbonates, even at the boiling heat, is completely prevented by the presence of a certain quantity of an alkaline monochromate.

Selenate of barium is easily and completely decomposed by solutions of alkaline carbonates, even at ordinary temperatures: this salt is somewhat soluble in water, and more readily in dilute acids.

Oxalate of calcium is decomposed by alkaline carbonates, even at ordinary temperatures; but to effect complete decomposition, the liquid must be frequently decanted and renewed. The decomposition takes place rapidly at the boiling heat; but in all cases it is completely prevented by the presence of a certain quantity of a neutral alkaline oxalate. When the salts are mixed in equivalent proportions, $\frac{3}{17}$ of the oxalate of calcium are decomposed at ordinary temperatures, and $\frac{5}{8}$ on boiling. Carbonate of calcium is partially converted into oxalate by the action of a solution of neutral oxalate of potassium at ordinary temperatures, and more quickly on boiling; but the decomposition is never complete, even when the liquid is frequently decanted and renewed. —Oxalate of lead is completely converted into carbonate at ordinary temperatures by the solution of an alkaline carbonate, a small portion of the carbonate of lead dissolving in the liquid. (Rose.)

The preceding experiments exhibit in a remarkable manner the influence of difference of solubility in determining the order of decomposition. Sulphate of barium is less soluble than the carbonate, and, accordingly, carbonate of barium is more readily decomposed by alkaline sulphates than the sulphate by alkaline carbonates. Precisely the contrary relations are exhibited by the sulphates and carbonates of strontium[*] and calcium, both as regards solubility and order of decomposition. On the other hand, oxalate of calcium is less soluble than the carbonate, and yet its decomposition by alkaline carbonates takes place more easily than the opposite reaction; in this case, the order of decomposition appears rather to be determined, as in Malaguti's experiments (p. 862), by the tendency of the strongest acid to unite with the strongest base.

The effect of a soluble sulphate, &c. in arresting the decomposition of the corresponding insoluble salts by alkaline carbonates, is evidently due to its tendency to produce the reverse action: hence the acceleration produced by decanting and renewing the liquid. Some insoluble salts, however, phosphate of calcium for example, are never completely decomposed, even by this treatment. (See also Malaguti, Ann. Ch. Phys. [3] li. 328.)

Theories of Chemical Action.

Chemical combination was in early times attributed to the general principle of Hippocrates that "like assorts with like:" hence the word *Affinity*, which seems to have been first employed by Barchhusen. Becher assumed, in accordance with this dogma, that when two bodies are capable of combining, they must contain a common

---

[*] According to Fresenius, carbonate of strontium dissolves in 11,862 parts, and sulphate of strontium in 6895 parts of water.

principle. Others, among whom was Lemery, supposed that solvents are furnished with a number of sharp points, by means of which they are more or less adapted to insinuate themselves into the pores of solid bodies and combine with them.

Dismissing these crude notions, we have to consider four distinct hypotheses which have been proposed to account for the phenomena of chemical action.

1. *Chemical combinations are produced by universal attraction.*

Newton was the first who referred chemical combination to universal attraction, though he did not regard the attraction between ultimate particles as exactly the same with that which acts between the great bodies of the universe.

Berthollet also regarded chemical combination as a manifestation of the force of universal attraction, exhibiting peculiar characteristics, because it is exerted, not on masses, but on molecules placed at extremely small distances from each other. Being unacquainted with the laws of combination in definite proportions, he supposed that bodies, by virtue of their affinity, are essentially capable of uniting in all proportions, and attributed what he considered the apparent exceptions to the law, entirely to the influence of cohesion and elasticity. That these causes exert considerable influence on chemical combination, is sufficiently evident from the phenomena already discussed; but to suppose that combination in definite proportion is absolutely dependent upon them, would be inconsistent with our present knowledge of the constitution of chemical compounds; indeed, the single fact that chlorine and hydrogen unite in one proportion only, and form hydrochloric acid gas, without any condensation or expansion, is quite sufficient to show the untenability of such a supposition.

2. *Chemical combinations are produced by a peculiar power called Affinity, distinct from all others.* This hypothesis may be reserved for discussion after it has been shown that all the known powers of nature are insufficient to account for the phenomena of chemical action.

3. *The union of heterogenous atoms is the result of Electrical attraction.*

Numerous theories of this kind have been proposed, among others by Davy, Dumas, Becquerel, Ampère, Grotthuss, Schweigger, Fechner, Berzelius and L. Gmelin.

Berzelius supposed that "The atom of every substance has two poles, on which the opposite electricities are accumulated in different proportions, according to the nature of the bodies. The atom of many bodies, oxygen for instance, has a large quantity of negative electricity attached to one of its poles, and but a very small quantity of positive electricity at the other; that of other bodies, potassium for example, has a large quantity of positive electricity at one pole, and a very little negative electricity at the other. Thus the elementary substances are divided into *electro-negative* and *electro-positive.* To each element, however, there belongs a particular proportion between the quantities of the two electricities. Oxygen has, of all the electro-negative elements, the greatest quantity of negative electricity at one of its poles, and the smallest quantity of positive electricity at the other,—then follows sulphur, then nitrogen, &c., and lastly hydrogen, in which the quantities of the two electricities are nearly equal. Of all electro-positive substances, potassium has the largest quantity of positive and the smallest of negative electricity; and this inequality continually diminishes in other bodies, till we come to gold, in which the positive electricity predominates but little over the negative—so that this element occupies the next place to hydrogen. According to this, the elements succeed one another in the electro-chemical series of Berzelius as follows, beginning with the electro-negative.

"*Electro-negative*, O, S, N, F, Cl, Br, I, Se, P, As, Cr, V, Mo, W, B, C, Sb, Te, Ta, Ti, Si, H.

"*Electro-positive*, Au, Os, Ir, Pt, Rh, Pd, Hg, Ag, Cu, U, Bi, Sn, Pb, Cd, Co, Ni, Fe, Zn, Mn, Ce, Th, Zr, Al, Y, G, Mg, Ca, Sr, Ba, L, Na, K.

"In the combination of an electro-negative with an electro-positive body, the predominant negative electricity of the former unites with the predominant positive electricity of the latter. Before, however, combination takes place, the former substance exhibits negative, and the latter positive electricity in the free state; and the tension of the two electricities continually increases as the bodies approach the temperature at which combination takes place. Hence we have an explanation of *electricity by contact.* At the instant of combination, the negative poles of the atoms of the first body turn themselves towards the positive poles of those of the second; and since it is only in the fluid state that the atoms possess the mobility necessary for this arrangement, it follows that solid bodies have, generally speaking, no chemical action on one another The two electricities of these poles now combine and produce heat or fire, whereupon they disappear. In every chemical combination, therefore, a neutralisation of the opposite electricities takes place, by which heat or fire is produced in the same manner as in the discharge of the electrical pile or of lightning, excepting that these last-mentioned phenomena are not accompanied by any chemical combination, at least of ponderable bodies. Every chemical combination is therefore an electrical phenomenon depending on the electrical polarity of the atoms."

The main difficulty of this theory is to account for the force by which combined atoms are held together. The heterogeneous atoms unite in consequence of their adhesion to the opposite electricities; but when these have been neutralised by combination, it might be expected that the atoms would fall asunder and allow themselves to be easily separated by friction and other mechanical forces, which is not the case. This objection to the theory of Berzelius has never been satisfactorily answered.

Gmelin's theory is as follows:—"Ponderable bodies have affinity for one another. The two electricities are substances which likewise possess affinity for each other, and by whose combination in the proportions in which they neutralise each other, heat (fire) is produced. The individual electricities, and likewise heat, have considerable affinity for ponderable substances, and are united to them with greater force and in greater quantity, the more simple these ponderable substances are. Ponderable bodies, according to their nature, have a greater or less excess of positive or negative electricity united with them, in addition to a definite quantity of heat. Thus, oxygen probably contains the greatest quantity of *positive*, and potassium of *negative* electricity. Bodies lying between these two extremes, contain a larger quantity of heat with a smaller excess of one or the other kind of electricity, the proportion of which varies greatly according to their nature.

"The combination of two ponderable bodies is the result of two forces, viz. the affinity of the ponderable bodies for each other, and the affinity of the electricity which is in excess in the one body for the opposite electricity which predominates in the other. By these two forces, the affinity of the electro-negative body for the positive electricity united with it, and that of the electro-positive body for the negative electricity combined with it, are overcome. The result is heat and the ponderable compound. The latter retains the excess of positive or negative electricity, by which it requires either an electro-negative or electro-positive character, and likewise part of the heat—while another portion is set free, and gives rise to the development of heat or fire, by which most chemical combinations are accompanied. When combination takes place between two bodies, both of which contain an excess of the same kind of electricity, *e.g.* oxygen and sulphur, which contain free positive electricity in different quantities,—it is simplest to suppose that the combination is the result merely of the affinity between the two ponderable bodies, that the new compound contains the sum of the excesses of positive electricity, and that the development of heat is a consequence of the inability of the new compound to retain as much heat united with it as was before combined with its constituents." (Gm. i. 154—158.)

4. *Chemical action results from a constant motion among the ultimate particles of bodies, this same movement likewise giving rise to the phenomena of heat, light, and electricity.* This is the theory suggested by Williamson (Chem. Soc. Qu. J. vi. 110). The atoms of all compounds, whether similar or dissimilar, are supposed to be continually changing places, the interchange taking place more quickly as the atoms resemble each other more closely. Thus, in a mass of hydrochloric acid, each atom of hydrogen is supposed, not to remain quietly in juxtaposition with the atom of chlorine with which it happens to be first united, but to be continually changing places with other atoms of hydrogen, or, what comes to the same thing, continually becoming associated with other atoms of chlorine. This interchange is not perceptible to the eye, because one molecule of hydrochloric acid is exactly like another. But suppose the hydrochloric acid to be mixed with a solution of sulphate of copper (the component atoms of which are likewise undergoing a change of place): the basylous elements, hydrogen and copper, then no longer limit their change of place to the circle of atoms with which they were at first combined, but the hydrogen and copper likewise change places with each other, forming chloride of copper and sulphuric acid. Thus it is that, when two salts are mixed in solution, and nothing separates out in consequence of their mutual action, the bases are divided between the acids, and four salts are produced. If, however, the analogous elements of the two compounds are very dissimilar, and, consequently, interchange but slowly, it may happen that the stronger acid and the stronger base remain almost entirely together, leaving the weaker ones combined with each other. This is strikingly seen in a mixture of sulphuric acid (sulphate of hydrogen) and borate of sodium, which soon becomes almost wholly converted into sulphate of sodium and free boracic acid (borate of hydrogen).

Now, suppose that, instead of sulphate of copper, sulphate of silver is added to the hydrochloric acid. At the first moment, the interchange of elements may be supposed to take place as above, and the four compounds, H^2SO^4, Ag^2SO^4, HCl, and AgCl, to be formed; but the last being insoluble, is immediately removed by precipitation; the remaining elements then act upon each other in the same way, and this action goes on till all the chlorine or all the silver is removed in the form of chloride of silver; if the original compounds are mixed in exactly equivalent proportions, the final result is the formation of only two salts, viz. in this case, $H\,SO^4$ and AgCl. A similar result is produced when one of the products of the decomposition is volatile at the existing temperature, as when hydrate or carbonate of sodium is boiled with chloride of ammonium.

If no precipitation or volatilisation takes place, and one of the compounds (hydrochloric acid) is in excess of the other (sulphate of copper), then, as the atoms of copper in their several interchanges must come in contact with chlorine-atoms more frequently than with SO^4-atoms, the final result must be the formation of a larger quantity of chloride of copper and of sulphate of hydrogen than if the bodies had been mixed in equivalent proportions, this effect of course increasing as the relative quantity of hydrochloric acid is greater in the original mixture; and thus we have an explanation of the effect of mass in chemical reaction.

The same theory affords an easy explanation of certain chemical changes otherwise somewhat obscure. Consider, for example, the formation of ether by the action of sulphuric acid upon alcohol, whereby ethyl-sulphuric acid (sulphate of ethyl and hydrogen) is first formed, and afterwards, at a certain temperature, ether and water are eliminated (p. 76). When alcohol, $\left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O$, and sulphuric acid, $\left.\begin{matrix}H\\H\end{matrix}\right\}SO^4$, are mixed together, the interchange between the atoms of ethyl in the former and of hydrogen in the latter gives rise to the formation of ethyl-sulphuric acid and water:

$$\left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O + \left.\begin{matrix}H\\H\end{matrix}\right\}SO^4 = \left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}SO^4 = \left.\begin{matrix}H\\H\end{matrix}\right\}O.$$

But the change does not stop here: for the ethyl-sulphuric acid thus produced, meeting with fresh molecules of alcohol, exchanges its ethyl for the hydrogen of the alcohol, producing ether and sulphuric acid:

$$\left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}SO^4 + \left.\begin{matrix}C^2H^5\\H\end{matrix}\right\}O = \left.\begin{matrix}C^2H^5\\C^2H^5\end{matrix}\right\}O + \left.\begin{matrix}H\\H\end{matrix}\right\}SO^4.$$

The sulphuric acid is thus restored to its original state, and is ready to act upon fresh quantities of alcohol; so that if alcohol be allowed to run into the mixture in a constant stream, the temperature being kept within certain limits (between 130° and 140° C.), the process goes on without interruption, ether and water continually distil over, and the same quantity of sulphuric acid suffices for the etherification of an unlimited quantity of alcohol. This is the peculiarity of the process; it has given rise to a variety of explanations, all more or less unsatisfactory, the discussion of which would be foreign to the present purpose; it is sufficient to remark that the hypothesis of atomic interchange affords a ready explanation of the chief peculiarity of the reaction, viz. the formation and decomposition of ethyl-sulphuric acid following each other continuously, without any change of temperature or other determining cause. If it be admitted that the atoms of ethyl and hydrogen in the mixture are continually interchanging in all possible ways, this series of alternate actions follows as a necessary consequence.

The idea of atomic motion is in accordance with physical as well as chemical phenomena. To suppose that rest, rather than motion, is the normal state of the particles of matter, is at variance with all that we know of the effects of light, heat, and electricity. In the theory of heat, the particles of bodies are supposed to be affected with progressive, as well as with rotatory and vibratory movements; and this same hypothesis of progressive movement, which of course implies change of relative position amongst the particles, affords, as already stated, an easy explanation of certain chemical reactions otherwise difficult to understand.

CHENOCHOLIC ACID. $C^{27}H^{44}O^4$. — An acid obtained by boiling taurochenocholic acid, the sulphuretted acid of goose-bile, with baryta-water, and decomposing the resulting barium-salt with hydrochloric acid. It is insoluble in water, but soluble in alcohol and ether, whence it separates as an amorphous mass. The solutions have an acid reaction, and give the characteristic blood-red colour with sugar and sulphuric acid. It is insoluble in cold potash, but when heated with it, forms a salt which, when freed from excess of potash, dissolves readily in water and in alcohol. The *barium*-salt consists of $C^{27}H^{43}BaO^4$. (Heintz and Wislicenus, Pogg. Ann. cviiii. 547.)

CHENOCOPROLITE. An impure iron sinter, containing a little silver and arsenate of cobalt. It is a product of decomposition, not a distinct mineral.

CHENOPODIUM. The herb of *Chenopodium ambrosioïdes* yields by distillation, a pure greenish-yellow volatile oil (about 1½ oz. from 10 lb.) having an aromatic and cooling taste (H. Becker, Zeitschr. Pharm. 1854, p. 8). According to Hirzel (*ibid.*) this oil, dehydrated by chloride of calcium and rectified, yields a colourless distillate boiling at 179° to 181° C.

Chenopodium maritimum.—The ash of this plant, growing on a strip of land reclaimed from the sea, has been analysed by Harms (Ann. Ch. Pharm. xciv. 247) with the following results: *a.* Flowers and young shoots. *b.* Stems.

	K^2O	Na^2O	Ca^2O	Mg^2O	Fe^4O^3	CO^2	SO^3	SiO^2	NaCl	
a.	4·4	2·3	4·2	6·6	4·3	0·9	3·0	2·4	71·9	= 100
b.	3·1	5·0	4·4	2·0	2·5	0·8	3·3	2·0	76·9	= 100

Traces of manganese were also found. The flowers and young shoots are said to yield 31·9 per cent. ash, and the stems 24·3 per cent. This, together with the very large proportion of chloride of sodium in the ash, seems to show that the plants analysed were saturated with salt water. *Aster tripolium* grown on the same soil, likewise yielded a very large amount of ash, containing about 65 per cent. NaCl in the stem and leaves, and 30 per cent. in the flowers.

Chenopodium olidum.—This plant contains an alkaloid having the composition C^3H^9N, either trimethylamine or propylamine, to which its fœtid odour appears to be due. (Dessaignes, Compt. rend. xxxiii. 358.)

Chenopodium Quinoa.—According to Völcker (Chem. Gaz. 1851, p. 129) quinoa seeds dried at 100° C. contain 46·10 per cent. starch, 6·10 sugar and extractive matter, 4·60 gum, 5·74 oil, 8·91 casein with a little soluble albumin, 13·95 insoluble albumin and other albuminoïdal compounds, 9·53 vegetable fibre, 5·05 ash. The ash (after deduction of sand and charcoal) contained 36·76 per cent. potash, 1·31 chloride of sodium, 2·45 lime, 13·61 magnesia, 1·78 ferric oxide, 38·99 phosphoric anhydride, 3·36 sulphuric anhydride, and 2·19 silica.

CHERT. A term often applied to hornstone and to any impure flinty rock, including the jaspers. (See *Ure's Dictionary of Arts, Manufactures and Mines*, i. 655.)

CHESSYLITE or **CHESSY COPPER.** Syn. with AZURITE. (See CARBONATES OF COPPER, p. 784.)

CHESTERLITE. See FELSPAR.

CHESTNUT. *Castanea vesca.*—The fruit of this plant has been examined by Payen (J. Pharm. [3] xvi. 279) and by Albini (Wien. Akad. Ber. xiii. 502). Payen found in 100 pts.:

	Water.	Ash in dry Substance.	Nitrogen.		
			In fresh Substance.	In dry Substance.	After deducting Ash.
Of the cultivated chestnut . .	54·21	4·04	0·53	1·17	1·21
Of the wild chestnut . . .	48·06	3·21	0·50	0·96	0·99

Albini found in the shelled kernels of dried chestnuts from various parts of Italy: 3·0—3·3 per cent. ash, 1·2—2·1 fat, 23·2—38·0 starch, 22·8—23·3 dextrin, 17·5—17·9 sugar, 6·5—8·4 cellulose, 0·9—2·1 vegetable albumin, and 5·2—5·3 so-called protein-compounds.

According to Dessaignes (J. Pharm. [3] xxv. 28), chestnuts contain a little asparagine, but no quercite.

The entire fruit of the tree (undried) yields 0·99 per cent. ash, containing in 100 pts. 39·36 K^2O, 19·18 Na^2O, 7·84 Ca^4O, 7·84 Mg^2O, 5·48 Mn^4O^3 [?], 3·88 SO^3, 2·32 SiO^2, 7·33 P^2O^5, 1·9 phosphates of calcium, magnesia, and iron, 4·82 NaCl. (T. Richardson, Jahresber. f. Chem. i. 1074.)

CHIASTOLITE. *Hollow Spar. Macle.* $Al^4O^3.SiO^2$.—A variety of Andalusite crystallised in right rhombic prisms with angles of 91° 35′ and 88° 27′. On looking into the end of the prism, we perceive in the axis of it a blackish prism, surrounded by the other, which is of a greyish, yellowish, or reddish-white colour. From each angle of the interior prism, a blackish line extends to the corresponding angle of the exterior. In each of these outer angles there is usually a small rhomboïdal space, filled with the same dark substance which composes the central prism. The black matter is the same clay-slate with the rock in which the chiastolite is imbedded. Fracture, foliated, with double cleavage. Translucent. Scratches glass. Rubbed on sealing-wax it imparts negative electricity. Specific gravity 2·94. Hardness 3—7·5. Before the blowpipe it is convertible into a whitish enamel. It has been found in Britany, in the Pyrenees, in the valley of Barège, and in Galicia in Spain, near St. Iago de Compostella. The interior black crystal is properly an elongated four-sided pyramid. U.

CHICA. A red dye, obtained from the leaves of *Bignonia Chica.* (See CARAJURU p. 747.)

CHILDRENITE. A phosphate of aluminium and iron (ferrosum) found with apatite at Tavistock in Devonshire, and at Crinnis in Cornwall. Rammelsberg found in two specimens:

	P^2O^5	Al^4O^3	Fe^2O	Mn^2O	Ca^2O	Mg^2O	H^2O	Total.
I. . .	29·36	18·77	30·75	6·12	0·66	—	17·00	102·66
II. . .	28·92	14·44	30·68	9·07	—	0·14	16·98	100·23

(after deducting 3·82 per cent. of insoluble residue in I. and 4·03 in II.)

From the analysis II., which was made with purer material than I., Rammelsberg deduces the formula: $2(4M^2O.P^2O^5) + 2Al^4O^3.P^2O^5 + 15H\ O$, which may be reduced to that of an orthophosphate with hydrate of aluminium and water, viz.: $(M^8al)P^8O^{12}.5alHO + 5aq$. The crystals belong to the trimetric system: $P . \frac{1}{2}P . 3\breve{P}\infty . \bar{P}\infty . \infty P$ and $0P$. Cleavage parallel to P and $\infty\breve{P}\infty$ (Brooke, Rammelsberg). Specific gravity = 3·247. Hardness = 5 (Rammelsberg). The crystals, which are transparent, have a glassy lustre, and vary in colour from yellowish-brown to blackish, are found on the surface of spathic iron ore intergrown with quartz, iron pyrites, and copper pyrites. (Brooke, Ann. Phil. vii. 316.—Rammelsberg, Pogg. lxxxv. 435; Phil. Mag. [4] iv. 118.)

CHILEITE. Syn. with GÖTHITE.

CHILTONITE. Syn. with PREHNITE.

CHINOLINE. C^9H^7N. *Quinoleine, Leucol* (Runge, Pogg. Ann. xxxi. 68.—Gerhardt, Ann. Ch. Pharm. xlii. 310; xliv. 279.—Hofmann, *ibid.* xlvi. 31; liii. 427; lxxiv. 15.—Bromeis, *ibid.* lii. 130.—Laurent, Ann. Ch. Phys. [3] xix. 367.—C. Greville Williams, Ed. Phil. Trans. xxi. [2]; [3] 377; Jahresber. d. Chem. 1855, p. 548; 1856, p. 532.—v. Babo, J. pr. Chem. lxxii. 73.—Gm. xiii. 243).—Runge, in 1839, obtained from coal-tar an organic base to which he gave the name of *leucol.* Gerhardt, in 1842, obtained a similar product, *quinoleine,* by distilling quinine and other organic bases with potash. Hofmann showed that Gerhardt's quinoleine and Runge's leucol were identical. Laurent first pointed out that Gerhardt's quinoleine was a mixture, a fact afterwards established by Gr. Williams, who separated pure chinoline from it, as well as from the mixture of bases obtained from coal-tar. According to later experiments by Williams, however, the chinoline from coal-tar appears to differ in some respects from that which is obtained from cinchonine, &c. Williams has also succeeded in preparing from chinoline (obtained from cinchonine), a fine blue colouring matter likely to be useful in dyeing.

Formation.—Chinoline is produced in numerous reactions:—1. In the dry distillation of coal, passing over with the tar (Runge).—2. By distilling cinchonine, quinine, or strychnine with hydrate of potassium (Gerhardt).—3. By the electrolysis of nitrate of cinchonine (v. Babo).—4. By distilling thialdine with milk of lime (Wöhler and Liebig, Ann. Ch. Pharm. lxi. v.)—5. By the dry distillation of trigenic acid or trigenate of silver (Liebig and Wöhler, *ibid.* lix. 289).—6. By distilling berberine with milk of lime, or hydrate of lead (Bödeker, Ann. Ch. Pharm. lxix. 43). Bödeker also states that chromate of pelosine heated to 100° C. gives off a mixture of chinoline and phenic acid; but according to Williams (Jahresber. d. Chem. 1848. p. 375), the only volatile products of this decomposition are methylamine. dimethylamine, and a pyrrol-base. Williams is of opinion that the production of chinoline in some of the above reactions has been inferred merely from its odour, when, in reality, not a trace of it has been present.

Preparation.—1. From *Cinchonine.* Pulverised cinchonine is gradually added to hydrate of potassium, which is heated in a retort till it melts; the mixture is then raised to a higher temperature till it becomes brown and emits stifling vapours (Gerhardt); and the distillate, which is a mixture of several bases, is boiled with an acid for several days, whereby pyrrhol is driven off. The dry chinoline which afterwards distils over, beginning to boil at 149° C., but not passing over in large quantities till the boiling point rises to 183°, is separated by repeated fractional distillation (about 200 times) into several portions, the lowest of which boils between 154° and 160°, and the highest, which is the largest in quantity, at 271°. Of these fractions, that which distils below 165° contains lutidine, with a little pyridine and picoline; that between 177° and 182° contains collidine, which is also found in the products up to 199°; and the portion which distils above 199°, especially that between 216° and 243°, consists of chinoline and lepidine, the latter being found chiefly in the portion boiling above 270°. To obtain chinoline (and the other bases) perfectly pure, the individual fractions are converted into platinum-salts, and separated by fractional crystallisation. (Williams.)

2. *From Coal-tar Oil.*—*a.* The mixture of phenylamine and chinoline (leucol), obtained from heavy coal-tar oil (see PHENYLAMINE), is dissolved in absolute alcohol, and neutralised with oxalic acid; and the mother-liquor decanted from the oxalate of phenylamine which has crystallised out, is distilled with potash, the receiver being changed as soon as the distillate no longer produces a blue colour with hypochlorite of calcium, and the chinoline which afterwards passes over is collected apart (Hofmann). Chinoline thus obtained, contains lepidine and other bases (Williams).—*b.* Fifty gallons of the oil of very high boiling point, and heavier than water, are treated with sulphuric acid, and the acid liquid is distilled with lime. The portion of the distillate which sinks in water, contains chinoline, lepidine, &c., together with a number of bases of the phenylamine series. The latter are decomposed with nitrite of potassium and hydrochloric acid (see PHENYLAMINE); the acid liquid is distilled from the heavy oil containing phenic acid; the admixed non-basic oils are expelled by passing steam through the liquid; the residue is filtered through charcoal; and the bases are separated from the aqueous solution by potash, and dried over sticks of solid potash. The mixture thus obtained yields, after more than a hundred fractional distillations, portions boiling between 177° and 274°, and from these the chinoline is separated by fractional crystallisation of the platinum-salts, as above. (Williams.)

Properties.—Chinoline is a transparent, colourless, strongly refracting, mobile oil, which neither thickens or freezes at $-20°$ C. (Hofmann, Bromeis). Specific gravity 1·081 at 10° (Hofmann). It conducts electricity less readily than phenylamine (Hofmann), boils steadily at 238° C. and distils without alteration (Williams): it evaporates even at ordinary temperatures, so that the oil-stain which it produces on paper soon disappears. The vapour-density of chinoline boiling between 238° and 243° C. is 4·519 (Williams). Chinoline has a penetrating odour, like that of phosphorus and of hydrocyanic acid (Runge), of St. Ignatius' bean (Gerhardt), of bitter-almond oil (Hofmann). It does not appear to be poisonous (Gerhardt). The aqueous solution kills leeches, but when introduced into the stomach of a rabbit, produces only transient convulsive symptoms and prostration of strength. It is alkaline to litmus and turmeric (Gerhardt, Bromeis); only to dahlia-paper (Hofmann).

Several formulæ have been proposed for chinoline. According to the analyses of Hofmann and Bromeis (made on chinoline containing lepidine, according to Williams), it is C^9H^8N; Gerhardt at first regarded it as $C^6H^{11}NO$, afterwards (*Traité*, iv. 449) as $C^{10}H^9N$. The formula C^9H^7N, first suggested by Laurent, is confirmed by Williams's analyses of several of the salts; the pure base does not appear to have been analysed. The formula C^9H^7N gives for the vapour-density, calculated to two volumes, the number 4·47 which agrees very nearly with Williams's determination.

Chinoline is very sparingly soluble in cold water, rather more in hot *water* and is extracted from the solution by ether (Hofmann). When shaken up with water at 0° C. it forms a clear oil containing $2C^9H^7N.3H^2O$, which at 15° C. gives up water and becomes turbid. When chinoline saturated with water at 0° C. is heated to 100°, water and a little chinoline escape, and a clear hydrate remains, containing $2C^9H^{17}N.H^2O$, which remains limpid and mobile at $-20°$, but is resolved by distillation into water and anhydrous chinoline. (Bromeis.)

Chinoline mixes in all proportions with *sulphide of carbon*, *alcohol*, *ether*, *wood-spirit*, *aldehyde*, and *acetone;* it also mixes with *oils*, both fixed and volatile. It dissolves *phosphorus*, *sulphur*, and *arsenic*, also common *camphor* and *colophony*, but not copal or caoutchouc. It does not coagulate albumin.

Decompositions.—1. Chinoline when set on fire, burns with a luminous but smoky flame.—2. It becomes resinised by exposure to the air.—3. *Chlorine* instantly changes it into a black resin, with great rise of temperature and evolution of hydrochloric acid (Hofmann), into a yellow oil, which is decomposed by water, leaving a white insoluble substance (Williams).—4. With *bromine*, it forms a similar resin (Hofmann).—5. Aqueous chinoline treated with a mixture of *hydrochloric acid* and *chlorate of potassium* rapidly becomes covered with a layer of orange-red oil, which solidifies to a tough mass on cooling (Hofmann).—6. *Fuming nitric acid* acts violently on chinoline, and converts it into a splendid mass of crystals, but does not form any products of decomposition (Gr. Williams).—7. Chinoline immediately takes fire in contact with dry *chromic acid*, and is resinised by aqueous chromic acid (Hofmann).—8. *Permanganate of potassium* decomposes chinoline into oxalic acid and ammonia Hofmann).—*Potassium* dissolves in chinoline, with evolution of hydrogen, but without colouring. On melting potassium in chinoline vapour, cyanide of potassium is formed. Chinoline vapour passed over burnt tartar, remains for the most part unchanged, but forms a small quantity of cyanide of potassium (Hofmann).—10. Chinoline passed over *red-hot quick lime* (Hofmann), or *soda-lime* (Bromeis), suffers little or no decomposition.—11. Enclosed in a sealed tube with *iodide of methyl*, and heated for ten minutes to 100° C., it is changed into crystals of hydriodate of methyl-chinoline. In like manner, it is converted by *iodide of ethyl* into hydriodate of ethyl-chinoline, and by *iodide of amyl* into hydriodate of amyl-chinoline (Williams).—12. Chinoline becomes warm when mixed with *sulphate of methyl* (sometimes disengaging vapour of methylic ether and methylic alcohol), and forms, if complete combination has been promoted by heat, a liquid soluble in water, which, when excess of sulphate of methyl is present, deposits separate crystals. The liquid is rendered turbid by potash or baryta, and separates oil-drops, which at first become red, then green, finally violet, and when heated pass into a beautiful violet resin, *methylirisine*, with formation of sharp, strongly smelling, condensable vapours. At the same time a brown resin and a sulphomethylate are formed. Chinoline, heated to boiling with *sulphate of ethyl*, forms a colourless liquid, which, when boiled with strong caustic potash, deposits a violet resin, *ethylirisine*, insoluble in ether, and a brown resin soluble in ether, while an ethylsulphate remains dissolved, and a sharp neutral oil, sinking in water, passes over, which, if immediately mixed with dichloride of platinum, yields beautiful needles, but soon decomposes (v. Babo).—13. *Chloride of acetyl* acts violently on chinoline, forming a crystalline very deliquescent mass (Williams).—14. With *cyanate of ethyl*, it solidifies into a crystalline mass consisting of phenyl-chinyl-carbamide, $N^2(CO)''.C^6H^5.C^9H^5.H^2$.

CHINOLINE SALTS.—Chinoline unites with acids, forming salts which crystallise easily (Williams). It precipitates salts of aluminium and ferricum, and renders lead-salts and ferrous salts slightly turbid (Hofmann). According to Gerhardt, it precipitates nitrate of silver, but not ferric nitrate.

Chinoline salts are decomposed by fixed alkalis; also by ammonia at a moderate heat; but at high temperatures, chinoline expels ammonia. Dry chinoline-salts treated with phenylamine, emit the odour of chinoline. (Hofmann.)

Chlorhydrate or *Hydrochlorate of Chinoline.*—Chinoline absorbs hydrochloric acid gas violently, and with evolution of heat, and solidifies on cooling to white crystals, which take up more hydrochloric acid, becoming red and liquid, and on again cooling, solidify to a deliquescent, slightly crystalline mass. Hence chinoline appears to form both a neutral and an acid hydrochlorate (Bromeis). When hydrochloric acid gas is passed over chinoline dissolved in ether, the hydrochlorate separates in heavy viscous drops, which after a while become slightly crystalline (Hofmann). Mixed with solutions of metallic chlorides, it forms double salts, which for the most part crystallise readily.

Chlorantimonite.—Chinoline forms with trichloride of antimony a white precipitate, which dissolves in boiling hydrochloric acid, and crystallises on cooling (Hofmann).

Chloro-aurate. $C^9H^7N.HCl.AuCl^3$.—Delicate canary-yellow needles, permanent in the air, sparingly soluble in water, and containing, when dried at 100° C. 41·85 per cent. of gold; the formula requires 42·0 per cent. (Williams.)

Chlorocadmate. $C^9H^7N.HCl.PtCl^2$.—The concentrated solutions of hydrochlorate of chinoline and chloride of cadmium solidify to a pulp when mixed: the dilute solutions yield white permanent needles, which give off 2 at. water at 100° C., volatilise completely at a higher temperature, and are sparingly soluble in alcohol. (Williams.)

Chloromercurate. $C^9H^7N.2HgCl$.—White precipitate, which is not decomposed by boiling water (Hofmann), and separates on cooling in beautiful pearly plates (Bromeis). It smells of chinoline, and has a very bitter, disagreeably metallic taste. According to Hofmann's analysis, it contains 26·5 per cent. C, 17·6 Cl, and 49·9 Hg, the formula requiring 27·0 C, 17·75 Cl, and 50·0 Hg.

Chloropalladite. $C^9H^7N.HCl.PdCl$.—Chestnut-brown crystals, containing 20·96 per cent. Pd; by calculation 21·18 per cent. (Williams.)

Chloroplatinate. $C^9H^7N.HCl.PtCl^2$.—Yellow crystalline precipitate, which dissolves in 893 pts. of water at 15° C. (Williams). The salt obtained by fractional crystallisation, fourteen times repeated, from a portion of the bases (prepared from cinchonine, p. 869), boiling between 238° and 243°, yielded 32·36 per cent. C, 2·74 H, and 29·29 Pt, the formula requiring 32·06 C, 2·58 H, and 29·19 Cl. (Williams.)

Chlorostannite.—Hydrochlorate of chinoline forms with protochloride of tin, a yellow, heavy oil, which afterwards becomes crystalline, and dissolves with difficulty in alcohol. (Hofmann.)

Chloro-uranate. $C^9H^7N.HCl.(U^2O)Cl$.—Concentrated solutions of ammonio-chloride of uranyl and hydrochlorate of chinoline, solidify when mixed: dilute solutions yield beautiful yellow prisms, containing (at 100° C.) 31·87 per cent. C, 2·77 H, and 20·97 Cl, the formula requiring 32·05 C, 2·37 H, and 21·07 Cl. (Williams.)

Chromate of Chinoline. — Chromic acid forms a yellow crystalline precipitate with chinoline (Gerhardt, Hofmann). Dilute chromic acid added in excess to aqueous chinoline (obtained from cinchonine), throws down a small quantity of resinous matter, which becomes crystalline when rubbed with a glass rod, dissolves in boiling water after filtering and washing, and is deposited in brilliant needles on cooling. It detonates when heated, but not after addition of hydrochloric acid. The crystals gave by analysis, 45·08 per cent. C, 3·49 H, and 22·34 Cr, agreeing very nearly with the formula $2C^9H^7N.H^2O.2Cr^2O^3$ (Williams). Chinoline from coal-tar did not yield a crystallised compound with chromic acid, but only oily drops, even when the impurities which could be destroyed by chromic acid had been removed. (Williams.)

Nitrate of Chinoline.—Solution of chinoline in excess of nitric acid, leaves when evaporated over the water-bath, a pasty mass, which solidifies on cooling, and when crystallised from hot alcohol, forms white needles, permanent in the air, infusible at 100° C., and consisting of $C^9H^7N.HNO^3$ (Williams). Easily soluble in water and alcohol, insoluble in ether. (Hofmann.)

Oxalate of Chinoline, is a confused, radiating, unctuous mass, easily soluble in water, alcohol, and ether (Hofmann). An *acid oxalate*, $C^9H^7N.C^2H^2O^4$, is obtained on mixing a solution of 16·5 pts. oxalic acid in a small quantity of water with 243 pts. of chinoline, as a soft, white, crystalline mass, which when recrystallised from alcohol, forms slender needles having a silky lustre. It decomposes at 100° C., with evolution of chinoline. (Williams.)

When chinoline containing phenylamine is dissolved in alcohol or ether, and mixed with alcoholic oxalic acid, almost all the oxalate of phenylamine is deposited after a few hours, while oxalate of chinoline remains in solution. (Hofmann.)

Picrate of Chinoline resembles picrate of phenylamine. (Hofmann.)

Sulphate of Chinoline. — Crystallisable and deliquescent. (Gerhardt and Hofmann.)

Tannate of Chinoline.—Chinoline forms with infusion of galls, a yellowish-brown precipitate (Hofmann); a white flocculent precipitate, soluble in boiling water and in alcohol. (Gerhardt.)

Substitution-Derivatives of Chinoline.

METHYL-CHINOLINE, $C^{10}H^9N = N.H.CH^3.C^9H^5$. (Gr. Williams, Ed. Phil. Trans. xxi. [3] 577.)—Not known in the free state, at least in definite form. The *hydriodate* is obtained in fine crystals, by heating chinoline and iodide of methyl together to 100° C. in a sealed tube for ten minutes. It is decomposed by oxide of silver, forming iodide of silver, and an unstable, strongly alkaline solution, which when heated with potash emits a suffocating odour, probably arising from methylamine. The *platinum-salt*, $C^{10}H^9N.HCl.PtCl^2$, is obtained as a sparingly soluble salt, by decomposing the solution of the hydriodate with nitrate of silver, precipitating the excess of silver with hydrochloric acid, and adding dichloride of platinum to the filtrate.

ETHYL-CHINOLINE, $C^{11}H^{11}N = N.H.C^2H^5.C^9H^5$. (Gr. Williams, *loc. cit.*)

Chinoline treated with iodide of ethyl, as in the preparation of hydriodate of methylchinoline, yields, after distilling off the excess of iodide of ethyl, crystals of hydriodate of ethylchinoline. On treating these crystals with oxide of silver and water (if this is done in the water-bath, a volatile product escapes which attacks the eyes), and filtering off the iodide of silver, a colourless, strongly alkaline solution of ethylchinoline is obtained, which decomposes on evaporation in the water-bath, assuming a carmine colour, and on the edges emerald-green, afterwards changing to a beautiful blue. It expels ammonia from sal-ammoniac. It precipitates chloride of mercury and the salts of lead, iron, and copper.

Hydriodate of Ethylchinoline, $C^{11}H^{11}N.HI$, forms cubes when recrystallised from alcohol. It is more soluble in water than in alcohol. It gives by analysis, 46·5 per cent. C, 4·4 H, and 44·1 I, the formula requiring 46·3 C, 4·9 H, and 44·6 I.

At 100° C., it becomes transiently blood-red. It is decomposed by sulphate of silver, forming iodide of silver, and a liquid which is colourless at first, but on evaporation over the water-bath, assumes a carmine colour, dark blue at the edges, and when dry leaves a blackish-red mass having a coppery lustre. The mass forms with water a dark carmine solution, which is coloured scarlet by hydrochloric and nitric acids, and rose-red by ammonia: with potash, it forms a violet precipitate which is but sparingly soluble in water, but dissolves in alcohol, forming a carmine-red solution. Dichloride of platinum produces in the hydrochloric acid solution of the precipitate, a bulky, insoluble double salt, of a higher atomic weight than the platinum-salt of hydrochlorate of ethylchinoline.

Platinum-salt of Ethylchinoline. $C^{11}H^{11}N.HCl.PtCl$.—Golden-yellow, sparingly soluble precipitate.

Respecting v. Babo's compounds, *methyl-* and *ethyl-irisine*, which appear to be isomeric with methyl- and ethyl-chinoline, see p. 870; also the names of the substances themselves.

AMYL-CHINOLINE, $C^{14}H^{17}N = N.H.C^5H^{11}.C^9H^5$ (Gr. Williams, *loc. cit.*)—A mixture of chinoline and iodide of amyl heated in a sealed tube for several hours to 100° C., deposits beautiful crystals of the hydriodate, $C^{14}H^{17}N.HI$. The *platinum-salt*, $C^{14}H^{17}N.HCl.PtCl^2$, is sparingly soluble in water, insoluble in ether-alcohol.

Hydriodate of amyl-chinoline heated with alkalis, yields a fine blue colour, which may be used as a dye. To prepare it, 1 pt. by weight of crude chinoline is to be boiled for ten minutes with 1½ pts. of iodide of amyl. The mixture, from being straw-coloured becomes deep reddish-brown, and solidifies on cooling to a mass of crystals. This product of the reaction is to be boiled for about ten minutes with 6 pts. of water, and, when dissolved, filtered through paper. The filtered liquid is to be gently boiled in an enamelled iron pan over a small fire, and excess of ammonia gradually added. The ebullition may be prolonged with advantage for one hour, the evaporation of the liquid being compensated for by the gradual addition of weak solution of ammonia, prepared by the admixture of equal volumes of ammonia of the density of 0·880 and distilled water. The hour having elapsed, the whole is allowed to cool, when the colour will almost entirely have precipitated, leaving the supernatant liquid nearly colourless. On pouring the fluid away (preferably through a filter, in order to retain floating particles of colour) the dish will be found to contain resinous looking masses which dissolve readily in alcohol, yielding a rich purplish-blue solution, which may be filtered and kept for use.

The colour prepared as above is of a purplish tint, but if a purer blue be required the following modification is to be resorted to. The filtered aqueous solution of hydriodate of amyl-chinoline, is, as before, to be brought to the boiling temperature; but instead of adding ammonia, a solution of caustic potash containing about one-fifth of its weight of solid potash is to be substituted. The addition is to be continued at intervals until three-fourths as much potash has been added as is equivalent to the iodine in the iodide of amyl used. The fluid may, after a quarter of an hour's ebullition, be filtered to separate the resinous colour. The product is a gorgeous blue with scarcely any shade of red. On adding the other fourth of potash to the filtrate while gently boiling, a black mass will be precipitated containing all the red, which otherwise would have been mixed with the blue. This mass dissolves readily in alcohol, yielding a rich purple solution containing, however, an excess of red. The alcoholic solution, on filtration, leaves on the filter a dark mass soluble in benzene, and as sometimes prepared, affording a brilliant emerald-green solution of great beauty. It is not always easy to obtain this green colour.

It is only the chinoline prepared from cinchonine that yields these colouring matters: a fact which points to an essential difference between this product and the isomeric base found among the products of the distillation of coal. Cinchonine distilled with excess of potash, yields about 65 per cent. of crude chinoline; and all the distillate which, on rectification (p. 869), distils above 199° or 209° C. (390° or 408° F.), up to the highest range of the mercurial thermometer, is suitable for the preparation of the colour. One pt. of this distillate and 1½ pts. iodide of amyl, yield 23 pts. of blue dye containing 4 per cent. of solid colouring matter. (Gr. Williams, *Chemical News*, 1861, p. 219.)

Chinoline-violet and chinoline-blue are resinous substances, which present a coppery appearance by reflected light, but when in very thin layers, appear of a violet or blue colour by transmitted light. They are bases and dissolve in acids, forming pale red solutions, which ammonia restores to their original colours. They are slightly soluble in hot water. Tannin precipitates them from their aqueous solutions, apparently forming an insoluble compound. Reducing agents do not affect their shade of colour. (W. H. Perkin, Chem. Soc. Qu. J. xiv. 246.)

Two volumes of chinoline-blue mixed with 1 vol. of Magenta pink (fuschine), of the ordinary strength found in commerce, form a fine purple inclining to blue (**Williams**). When chlorine is passed through an alcoholic solution of chinoline-blue, a green liquid is produced, which is perhaps the green spoken of by Williams. (Perkin.)

CHINONE. Syn. with QUINONE.

CHIOLITE. A fluoride of aluminium and sodium, $Na^3Al^4F^9$, occurring at Miask in the Ural, in snow-white, translucent, octahedral crystals, of the dimetric system, in which the principal is to the secondary axes as 1·077 : 1; also massive, granular resembling cryolite, with crystalline structure. Specific gravity 2·72 (Hermann); 2·842—2·898 (Rammelsberg). Hardness = 4. Analysis by Hermann (J. pr. Chem. **xxxvii**. 188), gave 23·78 per cent. Na, 18·69 Al, the formula requiring 23·4 and 18·6. Fuses easily before the blowpipe, and gives the reaction of fluorine. (Dana, ii. 98.)

CHITIN (from χιτων, a tunic). (Odier, Mém. Soc. d'Hist. Nat. de Paris, i. 29.—Lassaigne, J. Chim. méd. ix. 379; Compt. rend. xvi. 1087.—Payen, Compt. rend. xvii. 227.—C. Schmidt, *Zur vergleichenden Physiologie der wirbellosen Thiere.* 1845, p. 32; and Ann. Ch. Pharm. liv. 298.—Lehmann, Jahresber. d. ges. Med. 1844, p. 7.—Frémy, Ann. Ch. Phys. [3] xliii. 94; Schlossberger, Ann. Ch. Pharm. xcviii. 99.—Städeler, *ibid.* cxi. 21.—Gerh. *Traité*, iv. 535.—Pelouze et Frémy, *Traité*, vi. 93.)—The name given by Odier to the organic substance which forms the elytræ and integuments of insects and the carapaces of crustacea. It may be obtained by exhausting the wing-cases of cockchafers successively with water, alcohol, ether, acetic acid, and boiling alkalis. The final residue retains completely the form of the wing-cases. Frémy prepares chitin by treating the tegumentary skeleton of a crustaceous animal with cold dilute hydrochloric acid, to remove calcareous salts; washing with distilled water; boiling for several hours with solution of potash, which removes adhering albuminous substances, and has no action upon chitin; again washing with distilled water; and purifying the residue with alcohol and ether.

Chitin thus prepared is solid, transparent, of horny aspect, insoluble in water, alcohol, and ether. It is coloured brown by solution of iodine. Alkalis have no action upon it. By boiling with dilute acids, it is resolved into glucose and a nitrogenous compound. (Städeler.)

When chitin (from the carapace of the crab) is boiled for several hours with dilute sulphuric acid, only the softer membranes are attacked, while the more solid integuments become loose and soft, and form, after pressing and washing with water, a mass having almost the consistence of starch. The acid liquid supersaturated with lime, and then neutralised with sulphuric acid, yields neither tyrosine nor leucine, but contains ammonia, together with amorphous sugar, inasmuch as it precipitates cuprous oxide abundantly from an alkaline solution of cupric oxide (Städeler). Berthelot (Ann. Ch. Phys. [3] lvi. 149) likewise obtained sugar from chitin (prepared from the integuments of lobsters, crabs, and cantharides,) by macerating it in strong sulphuric acid till it was dissolved, dropping the solution into one hundred times its volume of boiling water, boiling for an hour, saturating with chalk, &c.

The above-mentioned pasty residue is coloured brown-red by iodine, like unaltered chitin, and by prolonged boiling with sulphuric acid, yields an additional quantity of sugar, while the undissolved portion always contains nitrogen. The same substance, after removal of the acid, forms with water a turbid emulsion, which takes a long time to clarify, and dries up by spontaneous evaporation to a soft skin-like membrane, which exhibits, with iodine-water, the same reactions as the original chitin. (Städeler.)

The composition of chitin is determined by the following analyses:—

	Schmidt. Mean of 11 analyses.	Lehmann.	Schlossberger.	Städeler.	*Calculation* $C^9H^{15}NO^6$.
Carbon . . .	46·64	46·73	46·64	46·32	46·35
Hydrogen . .	6·60	6·59	6·60	6·65	6·44
Nitrogen . .	6·56	6·49	6·56	6·14	6·01
Oxygen . .	40·20	40·19	40·20	40·89	41·20
	100·00	100·00	100·00	100·00	100·00

Frémy found in chitin 43·35 carbon, 6·65 hydrogen and no *nitrogen*, whence he regards chitin as isomeric with cellulose (44·4 C, 6·2 H, and 49·4 O). Gerhardt regarded Frémy's results as more correct than those of the German chemists, because chitin yields by dry distillation only acetic acid and empyreumatic oil, without any ammonia, and the products of its putrefaction under water are different from those of most nitrogenous substances. But the analyses above given exhibit a closeness of agreement which could scarcely be expected if the substances operated upon had been impure. (See CELLULOSE, p. 818.)

Städeler regards chitin as a glucoside, $C^9H^{15}NO^6$, which is resolved by boiling with acids into glucose and lactamide (or alanine or sarcosine):

$$C^9H^{15}NO^6 + 2H^2O = C^6H^{12}O^6 + C^3H^7NO^2.$$

If this decomposition really takes place, lactic acid should likewise be obtained as a product of the transformation of the lactamide or alanine; but the presence of lactic acid among the products has not yet been demonstrated. Städeler also suggests that chitin (at least in crustacea) may be formed by the union of lactate of ammonium with gum, and elimination of water:

$$[\underset{\substack{\text{Acid lactate of}\\\text{ammonium}}}{C^3H^4O^3.H.NH^4} + \underset{\text{Gum.}}{C^6H^{10}O^5} = \underset{\text{Chitin.}}{C^9H^{15}NO^6} + 2H^2O],$$

inasmuch as he has found gum in the juices of crabs and other crustacea, and the presence of lactic acid in the gastric juice of the lower animals is by no means improbable.

CHIVIATITE. A sulphide of lead and bismuth, also containing copper, from Chiviate in Peru, where it occurs, with pyrites and heavy spar, in foliated masses, cleavable in three directions in one zone, one making an angle with the second of 153°, and with the third of 133°. Specific gravity 6·920; colour lead-grey; lustre metallic. According to Rammelsberg's analysis (Pogg. Ann. lxxxviii. 320) it contains 18·00 S, 60·95 Bi, 16·73 Pb, 2·42 Co, 1·02 Fe, with trace of silver, and 0·59 insoluble matter (= 99·71), whence the formula $2(Pb^2;Cu^2)S.Bi^2S^3$. (Dana, ii. 77.)

CHLADNITE. See METEORITES.

CHLOANTHITE. Native arsenide of nickel containing cobalt, also called white nickel. (See NICKEL).

CHLOCARBETHAMIDE. Syn. with TRICHLORACETAMIDE (p. 6).

CHLORACETAMIC ACID. Syn. with TETRACHLORACETAMIDE (p. 6).

CHLORACETAMIDE. See ACETAMIDE (p. 6).

CHLORACETIC ACIDS. Two of these compounds are known, viz. *mono-* and *tri*-chloracetic acids, both being produced by the action of chlorine gas on glacial acetic acid under the influence of light, the former when the acid is in excess, the latter when the chlorine and the acetic acid are brought together in the exact proportions required for its formation. The trichlorinated acid is likewise produced in several other reactions. *Di*chloracetic acid has not yet been obtained, at least in definite form.

Monochloracetic Acid, or simply **Chloracetic Acid.** $C^2H^3ClO = C^2H^2ClO.H.O.$ (R. Hoffmann, Ann. Ch. Pharm. cii. 1.)—Dumas had observed that, in the preparation of trichloracetic acid by the action of chlorine on acetic acid in sunshine, a lower substitution-product is always obtained, especially if the acetic acid is in excess, in the form of an uncrystallisable acid, which however he did not succeed in preparing in the separate state. F. Leblanc afterwards obtained this acid, the monochloracetic acid, in the form of a colourless liquid, by passing chlorine through glacial acetic acid in the shade; his product however was not quite pure. More recently Hoffmann has shown that the chief product of the action of chlorine on excess of acetic acid in sunshine, is monochloracetic acid, and that this acid, when pure, is solid and crystalline at ordinary temperatures.

Preparation.—1. A tubulated retort of about 1 litre capacity and containing from half a pound to a pound of glacial acetic acid, is placed in a bath containing a saturated solution of nitrate of sodium (boiling at 120° C.), and dry chlorine gas is passed into the retort by a tube inserted through the tubulure and terminating just above the liquid, so that the gas may mix immediately with the vapour of the acid. The neck of the retort having a wide glass tube attached to it, is directed upwards, so that any acetic acid which evaporates undecomposed may be condensed and flow back again, while the hydrochloric acid and excess of chlorine escape. The whole apparatus is placed in the sunshine, and the evolution of chlorine is so regulated that the upper part of the retort always appears coloured by it. The stronger the light, the more rapid is the absorption of chlorine; but the action takes place, though slowly, even under a clouded sky. A very slow substitution of chlorine for hydrogen likewise takes place in the dark and at ordinary temperatures. As the formation of chloracetic acid goes on, the action slackens, so that it is best, after about fifteen hours' exposure to sunshine, or twice as long to diffused daylight, to expel the excess of chlorine from the apparatus by a steam of dry air, and rectify the product in a smaller retort. The portion which distils below 130° C. consists almost wholly of unaltered acetic acid, and may be used in a subsequent preparation. That which passes over between 130° and 190° is easily separated, by repeated rectification, into acetic and a thick liquid which boils between 185° and 187°, and either solidfies immediately into a mass of white needle-shaped crystals, or yields after some time, large, isolated, transparent, colourless rhombic tables, while the greater portion remains liquid, but if shaken up or stirred with a glass rod, solidifies suddenly and with considerable rise of temperature, the crystals previously formed becoming opaque and white like porcelain. The crystalline mass, which melts between 45° and 47°, consists of nearly pure monochloracetic acid, mixed however with a certain quantity of liquid, which may be removed by decantation and rapid pressure, and used, together with the portion of the original liquid which distilled below 130°, in a subsequent preparation. The expressed crystals are placed on bibulous paper and completely dried in vacuo over oil of vitriol and a few lumps of hydrate of potassium, and then redistilled, the first and last portions of the distillate being rejected. As they are very deliquescent, they should be kept as much as possible from the air. (Hoffmann.)

In the first distillation and in the subsequent rectifications, there is obtained a small quantity of a liquid which boils above 190°, and appears to contain an acetic acid with more than 1 at. hydrogen replaced by chlorine. It yielded in different experiments from 48 to 50 per cent. of chlorine, which does not agree with the formula either of dichloracetic (requiring 55·04) or of trichloracetic acid (requiring 65·13 per cent. of chlorine). In one experiment, this liquid, on being saturated with baryta, yielded, besides monochloracetate of barium, a small quantity of small, opaque, warty crystals, the composition of which seemed to show that they contained a higher chlorinated acid; but in no instance, even when the purest crystallised acetic acid was used and the absorption took place in the brightest sunshine, was any definite dichloracetic or trichloracetic obtained, the chief product being invariably monochloracetic acid. Neither was any oxalic acid formed, as in Dumas' preparation of trichloracetic acid (p. 877). (Hoffmann.)

2. Monochloracetic acid is also obtained in a state of purity by the action of water on monochlorinated chloride of acetyl. On distilling the liquid, the thermometer rises from 100° to 180°, and the liquid which passes over at that temperature solidifies in a crystalline mass on cooling. (Wurtz.)

Properties.—The acid crystallises from fusion in rhombic tables, having acute angles of 77° or 78°; from solution in acetic acid—*e.g.* from the liquids obtained in the first distillation between 180° and 186°, and between 186° and 190°—in crystals having a prismatic character, and very much resembling those of trichloracetic acid. Melting point 62°. It contracts strongly in solidifying, and generally gives off numerous air-bubbles. The specific gravity of the melted acid at 73°, is 1·366 as compared with water at 19°, and 1·3947 compared with water at 73°. Boiling point from 185° to 187·8°. It distils undecomposed, and when pure solidifies in the neck of the retort; but if mixed with acetic acid, remains liquid below its ordinary point of solidification. When kept for some time at a temperature near its melting point, it sublimes in long spicular crystals. It is nearly inodorous at ordinary temperatures, but its vapour has a pungent suffocating odour. It has a strong acid taste, attacks the cuticle, and raises blisters if kept on it for some time. It deliquesces in the air, and dissolves very easily in *water*, producing considerable fall of temperature.

Decompositions.—1. The acid is decomposed by *pentachloride of phosphorus*, with formation of oxychloride of phosphorus and monochlorinated chloride of acetyl, but the two chlorides cannot be separated by distillation, as they both boil at about 110°. When the product was repeatedly distilled with small portions of acid chloracetate of potassium, the residues of the last distillations yielded at high temperatures a large proportion of chloracetic acid, the last portions of which boiled as high as 200°, and had a more penetrating odour, probably arising from the presence of a small quantity of the anhydrous acid.—2. The acid heated with *potash-ley*, *ammonia*, *baryta-water*, or *lime-water*, immediately yields a chloride of the alkali-metal and glycollic acid. (Kekulé.)

$$C^2H^2ClMO^2 + H^2O = MCl + C^2H^4O^3.$$

3. Chloracetic acid is reduced by *potassium-amalgam* or *sodium-amalgam* to acetic acid, in the same manner as trichloracetic acid; the decomposition is however incomplete, and is attended with evolution of hydrogen. (Hoffmann.)

The CHLORACETATES, $C^2H^2ClMO^2$, are obtained by digesting the oxides or carbonates in the aqueous acid: they are for the most part easily soluble and crystallisable.

Chloracetate of Ammonium decomposes by evaporation like the potassium-salt. It is more soluble than that salt, and solidifies only from a perfectly viscid solution, in the form of a crystalline cake, which deliquesces on exposure to the air.

Chloracetate of Barium. $C^2H^2ClBaO^2 + H^2O$.—May be obtained, even with very small quantities of material, in distinct prismatic crystals, apparently belonging to the trimetric system, and containing 39·99 per cent. barium (by calculation 40·06). Decomposes but little during evaporation, and separates out almost completely on cooling from a hot saturated solution. (Hoffmann.)

Chloracetate of Potassium. *a. Neutral.* $2C^2H^2ClKO^2 + 3H^2O$.—Obtained by saturating the acid with carbonate of potassium and evaporating to a syrup in vacuo over oil of vitriol. It then separates in thin colourless laminæ, which may be obtained pure by draining on bibulous paper. It is not deliquescent, and does not give up its water of crystallisation at 100° C., but is decomposed at a higher temperature, yielding chloride of potassium, glycollic acid, and a small quantity of glycolide, $C^2H^2O^2$. (Kekulé, Ann. Ch. Pharm. cv. 288):

$$C^2H^2ClKO^2 = KCl + C^2H^2O^2.$$

It is also decomposed when its solution is evaporated at a gentle heat. It is very soluble in water. After drying in vacuo, it yielded 24·63 per cent. potassium (by calculation, 24·55).

b. Acid. $C^2H^2ClKO^2.C^2H^3ClO^2$.—When a solution of the neutral salt is mixed with as much acid as it already contains, the whole solidifies to a thick pulp of small white pearly crystals, which may be purified by draining on bibulous paper or by drying over oil of vitriol. Sparingly soluble in water.

Chloracetate of Silver. $C^2H^2ClAgO^2$.—A hot solution of the acid saturated with oxide of silver, yields the salt on cooling in splendid rhomboïdal, iridescent laminæ (Wurtz).—Anhydrous. Dissolves sparingly in cold, more readily in hot water, and is easily obtained by cooling, in small nacreous scales, which blacken on exposure to light, and yield chloride of silver. Between 110° and 120° C. it decomposes with a kind of explosion, emitting the same odour as the acid when it evaporates, and leaving chloride of silver, mixed with a very small quantity of metallic silver.

Chloracetate of Ethyl. $C^4H^7ClO^2 = C^2H^2ClO^2.C^2H^5$. (E. Willm, Ann. Ch. Phys. [3] xlix. 97.)—Obtained by the action of alcohol on monochlorinated chloride of acetyl:

$$C^2H^6O + C^2H^2Cl^2O = C^4H^7ClO^2 + HCl.$$

The action, which is very violent, must be moderated by cooling the vessel externally, and as soon as it is finished, the product may be washed with water, dehydrated by chloride of calcium and rectified.

Colourless liquid, having an ethereal odour and burning taste, heavier than water and insoluble in that liquid. Boils at 143°·5 C. when the barometer stands at 758° mm. Vapour-density 4·46.

The ether burns with a bright flame, green at the edges. It is decomposed by potash, into alcohol and chloracetic acid, which then suffers further decomposition, yielding chloride and acetate of potassium.

Trichloracetic Acid. $C^2HCl^3O^2 = C^2Cl^3O.H.O.$ (Dumas, J. Chim. méd. vi. 659; also Ann. Ch. Pharm. xxxii. 101; Ann. Ch. Phys. lxxiii. 75; Melsens, Ann. Ch. Phys. [3] x. 233; Malaguti, Ann. Ch. Phys. [3] xvi. 10; Kolbe, Ann. Ch. Pharm. liv. 182; Gm. ix. 209; Gerh. i. 749.)—This acid was discovered by Dumas in 1839. It is produced: 1. By the action of 6 at. dry chlorine gas on 1 at. glacial acetic acid in sunshine (Dumas):

$$C^2H^4O^2 + 6Cl = C^2HCl^3O^2 + 3HCl.$$

2. In the oxidation of soluble chloral by a mixture of hydrochloric acid and chlorate of potassium, and of chloral either soluble or insoluble, by fuming nitric acid (Kolbe):

$$C^2HCl^3O + O = C^2HCl^3O^2.$$

3. By the action of chlorine gas in sunshine on dichloride of carbon covered with a layer of water (Kolbe):

$$C^2Cl^4 + 2H^2O + Cl^2 = C^2HCl^3O^2 + 3HCl;$$

part of the C^2Cl^4 is at the same time converted into C^2Cl^6.—4. In the decomposition of chloride of trichloracetyl (chloraldehyde) by water (Malaguti):

$$C^2Cl^4O + H^2O = C^2HCl^3O^2 + HCl.$$

5. In the decomposition of perchlorinated formic ether by water (Cloez, Ann. Ch Phys. [3] xvii. 300):

$$C^3Cl^6O^2 + 2H^2O = C^2HCl^3O^2 + CO^2 + 3HCl.$$

Preparation.—1. When glacial acetic acid is exposed to the sun in bottles of 5 or 6 litres capacity (in the proportion of 0·8 or 0·9 grms. of the acid to 1 litre of chlorine) crystals of trichloracetic acid make their appearance in about a day, together with a small quantity of oxalic acid. On opening the bottles, a mixture of hydrochloric acid gas with a small quantity of carbonic acid and a suffocating vapour, escapes with force. The bottles are then left open for some hours, till the gaseous mixture is completely expelled, and washed out with a small quantity of water, whereby a concentrated solution of trichloracetic acid is obtained, mixed, however, with hydrochloric acid, undecomposed acetic acid, and oxalic acid. When this solution is evaporated in vacuo over oil of vitriol and hydrate of potassium, water, hydrochloric acid, and part of the acetic acid escape, and the solution then yields crystals, first of oxalic, afterwards of trichloracetic acid. The mother-liquor distilled with phosphoric anhydride, which decomposes the oxalic acid, yields a distillate of acetic acid, and then, on changing the receiver, of trichloracetic acid, which soon solidifies to a crystalline mass. Lastly, the crystals are left for some hours in vacuo on several sheets of white blotting paper, so that the admixed acetic acid may soak into the paper. (Dumas.)

2. Insoluble chloral is treated with fuming nitric acid, and the action, which is at first attended with evolution of heat and abundant evolution of red fumes, is afterwards assisted by the application of a gentle heat, till the flakes of insoluble chloral have completely disappeared; the greater part of the excess of nitric acid is then distilled off;

and the remaining portion is left to evaporate in vacuo over oil of vitriol and hydrate of potassium. Crystallised trichloracetic acid then remains, free from nitric, acetic, and oxalic acid, but generally retaining traces of chloral. (Kolbe.)

3. When dichloride of carbon, C^2Cl^4, is placed in a bottle filled with chlorine gas, covered with a film of water, and exposed to the sun, there is formed, besides C^2Cl^6, an aqueous solution of trichloracetic acid, which may be obtained in the crystalline state by evaporation in vacuo over oil of vitriol and lime. (Kolbe.)

4. Chloraldehyde is dissolved in water; and the solution containing hydrochloric acid is evaporated in vacuo over oil of vitriol and hydrate of potassium, whereby trichloracetic acid is obtained in beautiful crystals. (Malaguti.)

Properties.—Trichloracetic acid forms colourless rhombohedrons. It melts above 46° C., and in cooling begins to solidify at 45°; if the mass be then shaken, the temperature rises to 46°, which is therefore the melting point. In the fused state, it has a density of 1·617 at 46°, that of water at 15° being 1·000. Boils between 195° and 200° without any decomposition, and sublimes in the form of a silvery crust. Vapour-density = 5·3, by calculation 5·637, the difference arising from partial decomposition. The acid has a faint odour at ordinary temperatures, but when heated till it volatilises, it emits a pungent and suffocating odour. It has a caustic, sour taste, and makes the tongue white, like peroxide of hydrogen. It destroys the cuticle, causing it to peel off on the following day, and if left for some time on the skin, produces blisters. It reddens litmus strongly, but does not bleach it, even after a considerable time. It deliquesces in the air and dissolves readily in water. (Dumas.)

Decompositions.—1. When the acid is heated with *strong sulphuric acid*, part of it distils over unchanged, and crystallises in rhombohedrons; the rest is resolved into hydrochloric acid, carbonic anhydride, and carbonic oxide (Dumas). [Perhaps in this manner: $C^2HCl^3O^2 + H^2O = 3HCl + CO + CO^2$].—2. When it is heated with excess of *potash-solution*, ebullition takes place, continuing after the vessel has been removed from the fire; the first products of the action are chloroform and carbonate of potassium; but on further boiling with the alkaline liquid, the chloroform is resolved into formate and chloride of potassium. (Dumas.)—First:

$$C^2HCl^3O^2 + K^2O = CHCl^3 + K^2CO^3$$

then:

$$CHCl^3 + 2K^2O = CHKO^2 + 3KCl.$$

When the acid is boiled with baryta-water, carbonate of barium is precipitated and chloroform evolved (Dumas).—3. The acid boiled with excess of *ammonia*, is resolved into carbonate of ammonium, which sublimes, and chloroform, which sinks down as an oil (Dumas):

$$C^2HCl^3O^2 + (NH^4)^2O = (NH^4)^2.CO^3 + CHCl^3.$$

4. Aqueous trichloracetic acid, or either of its salts dissolved in water, is decomposed by *potassium-amalgam* (1 pt. potassium to 150 pts. mercury) with evolution of heat, and reconverted into acetate of potassium (Melsens). If the amalgam is not in excess in proportion to the acid, no hydrogen is evolved. Antimonide of potassium, or potassium alone, or zinc with sulphuric acid, does not effect the transformation, but causes an evolution of hydrogen gas (Melsens).—If instead of 6 at. potassium, only 3 at. be used in the form of potassium-amalgam, no acetic acid is produced, but apparently an acid containing a smaller quantity of chlorine than trichloracetic acid. 5. *Zinc* dissolves in aqueous trichloracetic acid, and forms, besides chloride of zinc, a zinc-salt which appears to contain dichloracetic acid $C^2Cl^2H^2O^2$. Trichloracetic acid is also reduced to acetic acid in the galvanic circuit of a two-pair Bunsen's zinc-carbon battery, with electrodes of amalgamated zinc. (Kolbe.)

TRICHLORACETATES.—Trichloracetic acid is monobasic, like acetic acid, the formula of its salts being $C^2MCl^3O^2$.

Trichloracetate of Ammonium. $C^2(NH^4)Cl^3O^2 + 2H^2O$.—The aqueous acid saturated with ammonia, and evaporated at ordinary temperatures, either in vacuo or in the air, yields crystals (Dumas). The salt is likewise produced when trichloracetamide is brought in contact with aqueous ammonia or very dilute nitric acid (Malaguti, Cloez). It crystallises in beautiful prisms (containing 2 at. water, melts at 80°; boils between 110° and 115° C., giving off vapours of chloroform and acid carbonate of ammonium, the latter appearing in peculiar abundance at 145°; and solidifies at 160° in yellowish, micaceous scales of anhydrous trichloracetate of ammonium, which are tasteless, dissolve readily in water, and give off ammonia when treated with potash, even in the cold. At a higher temperature, these scales fuse, and are resolved into carbonic oxide, phosgene, and sal-ammoniac vapour. (Malaguti.)

Decomposition of the crystallised salt:

$$C^2(NH^4)Cl^3O^2 + 2H^2O = CHCl^3 + NH^4.H.CO^3 + H^2O.$$

Decomposition of the anhydrous salt:

$$C^2(NH^4)Cl^3O^2 = CO + CCl^2O + NH^4Cl.$$

Trichloracetate of Potassium. $2C^2KCl^3O^2 + H^2O$.—The aqueous acid neutralised with carbonate of potassium yields by spontaneous evaporation, silky needles, which decompose with a kind of detonation when gently heated, and absorb only a small quantity of water when exposed to damp air. (Dumas.)

The *Barium* and *Calcium salts* are neutral and dissolve very readily in water. (Dumas.)

Trichloracetate of Silver. $C^2AgCl^3O^2$.—Recently precipitated oxide of silver immersed in the aqueous acid is converted into grey laminæ which dissolve in a larger quantity of water, and crystallise therefrom by evaporation in vacuo over oil of vitriol and in the dark, in crystalline granules and laminæ. The salt is very readily decomposed by light. When heated on a sheet of paper, it detonates violently, giving off the same odour as trichloracetic acid when it evaporates, and leaves vegetations of pure chloride of silver. If it be moistened with alcohol and the alcohol set on fire, it decomposes more quietly, and without projection. (Dumas.)

Trichloracetate of Ethyl. Trichloracetic Ether. $C^2Cl^3O^2.C^2H^5$.—Obtained either by distilling trichloracetic acid with alcohol and a small quantity of sulphuric acid (Dumas), or by gradually adding chloraldehyde to alcohol. (Malaguti.)

$$\underset{\text{Chloral-dehyde.}}{C^2Cl^4O} + C^2H^6O = C^2Cl^3O^2.C^2H^5 + HCl.$$

The product obtained by either of these processes is precipitated by water, washed with water, and dried over chloride of calcium. It is a colourless oil, smelling like peppermint. Specific gravity 1·367. Boiling point 164°. Vapour-density 6·64.

Aqueous *potash* decomposes it, forming alcohol and trichloracetate of potassium:

$$C^2Cl^3O^2.C^2H^5 + KHO = C^2H^6O + C^2Cl^3KO^2.$$

Ammonia converts into trichloracetamide, $N.H^2.C^2Cl^3O$ (p. 22).

Exposed to the action of chlorine in daylight, and in direct sunshine, it yields the same products as acetate of ethyl (p. 22). It is isomeric with the compound obtained by passing dry chlorine through dichloracetic ether contained in a vessel, the upper part of which is protected from the light. The two compounds are distinguished from each other by their behaviour with potash, the latter yielding, not trichloracetate of potassium, but chloride of potassium, deliquescent chlorinated potassium-salts, and a sweet oily liquid no longer decomposible by potash. (Leblanc.)

The higher chlorinated compounds produced by the action of chlorine on acetate of ethyl may be regarded as compounds of trichloracetic acid with ethyl in which the hydrogen is more or less replaced by chlorine: thus tetrachloracetic ether $C^4H^4Cl^4O^2 = C^2Cl^3O^2.C^2H^4Cl$; perchloracetic ether, $C^4Cl^8O^2 = C^2Cl^3O^2.C^2Cl^5$. All these compounds, indeed, when treated with potash, yield trichloracetate of potassium, *e.g.*:

$$C^4Cl^8O^2 + 2KHO = 2C^2Cl^3KO^2 + 2HCl.$$

Some of them however appear to be susceptible of isomeric modifications.

Trichloracetate of Methyl. $C^2Cl^3O^2.CH^3$.—Obtained by processes exactly similar to those which yield the ethyl-compound, viz. by distilling the acid with wood-spirit and sulphuric acid, or by the action of wood-spirit on chloraldehyde. It is a colourless oil, heavier than water, and smelling like peppermint. It is isomeric with the compound $C^3H^3Cl^3O^2$, obtained by the action of chlorine on acetate of methyl. The two compounds are not however identical; for the former is converted by potash into methyl-alcohol and trichloracetate of potassium (together with formate and chloride of potassium resulting from the further action of the potash, p. 45); the latter when treated with potash yields chloride and formate of potassium, together with chloromethylase, $CHCl$. (Laurent, see p. 23.)

Trichloracetate of methyl exposed to the action of chlorine in sunshine, is converted into perchloromethylic acetate, $C^3Cl^6O^2$, a compound also produced by the continued action of chlorine on acetate of methyl.

CHLORACETONES. See ACETONE (p. 29).

CHLORACETONITRILE. See ACETONITRILE (p. 33).

CHLORACETYL. C^2H^2ClO.—The radicle of chloracetic acid, chloracetamide, &c.

Trichloracetyl, C^2Cl^3O, is the radicle of trichloracetic acid, trichloracetamide, chloral, chloraldehyde, chloralide, &c.

CHLORACETYPHIDE. *Trichloracephosphide. Phosphide of Trichloracetyl and Hydrogen.* $C^2H^2Cl^3PO = P.H^2.C^2Cl^3O$.—This compound, the analogue of trichloracetamide, is produced by the action of chloride of trichloracetyl on phosphoretted hydrogen:

$$C^2Cl^3O.Cl + PH^3 = HCl + P.H^2.C^2Cl^3O,$$

also, together with oxychloride of carbon, when phosphoretted hydrogen is passed into heated perchloroformic ether:

$$C^3Cl^6O^2 + PH^3 = P.H^2.C^2Cl^3O + COCl^2 + HCl.$$

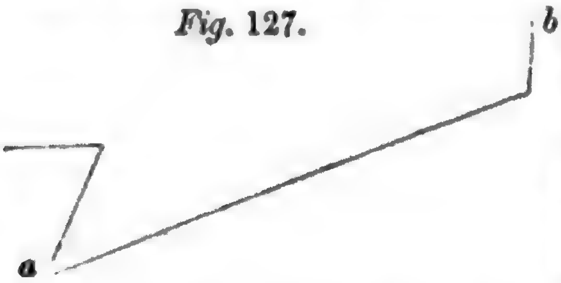
It forms small, white, crystalline scales, having a slightly alliaceous odour and bitter taste. It is permanent in the air at ordinary temperatures, but decomposes when heated, leaving a carbonaceous residue containing phosphoric acid. It is insoluble in water; slightly soluble in alcohol, ether, and wood-spirit. (Cloez, Ann. Ch. Phys. [3] xvii. 309.)

CHLORAL. *Hydride of Trichloracetyl.* $C^2HCl^3O = C^2Cl^3O.H$.—This body was discovered by Liebig in 1832 (Ann. Ch. Pharm. i. 189), and further examined by Dumas (Ann. Ch. Phys. [2] lvi. 123) and Städeler (Ann. Ch. Pharm. lxi. 101). It is the ultimate product of the action of chlorine upon alcohol:

$$C^2H^6O + Cl^8 = C^2HCl^3O + 5HCl.$$

Probably the alcohol is first converted into aldehyde by abstraction of 2H; and in this compound 3H are afterwards replaced by 3Cl (see ALCOHOL). Choral cannot, however, be obtained by the direct action of chlorine on aldehyde; it appears to be produced in the first instance, but is quickly converted into other products. For the production of chloral from alcohol, it is absolutely necessary that the alcohol be anhydrous; if water is present, aldehyde, acetal, acetic acid, acetic ether, and other products are formed instead of chloral; these products also accompany the chloral, even when the preparation is made with absolute alcohol (see ALCOHOL, *Decomposition by Chlorine*, p. 74). Chloral is also produced by the action of chlorine on starch or sugar. (Städeler.)

Fig. 127.



Preparation.—1. From alcohol. Pure and dry chlorine gas is passed into absolute alcohol contained in a tubulated retort having its neck directed upwards, and fitted with a long condensing tube, which passes down to the bulb, and projects considerably above the extremity of the neck to carry off uncondensed gases; the chlorine is introduced through the tubulus. Or the alcohol may be contained in a tube bent, as shown in *fig.* 127, the middle portion being 2 or 3 ft. long, and placed at a slight inclination, so that the chlorine entering at the lower part, may pass through a column of alcohol of considerable length but no great height. The chlorine is best evolved from a mixture of common salt, peroxide of manganese and sulphuric acid (which gives it off more regularly than hydrochloric acid and manganese); it must be passed first through a wash-bottle containing water, and then through sulphuric acid or over chloride of calcium, to dry it. The unabsorbed chlorine, together with hydrochloric acid gas and vapour of hydrochloric ether, may be passed into two Woulfe's bottles, and thence into the open air, so that the operator may not be annoyed by it. At the commencement of the operation, the alcohol is cooled by affusion of cold water, to prevent it from taking fire and depositing soot; but afterwards, when the absorption of the chlorine diminishes, and the liquid assumes a yellow colour, it must be gradually heated, and at last nearly to the boiling point; 200 grammes of alcohol require the passage of a rapid stream of chlorine to be continued for 15 or 20 hours, involving a consumption of about 1200 litres of chlorine gas. The alcohol becomes continually thicker, acquires a higher boiling point, and is finally converted into a heavy syrup, which, after standing for some days, solidifies completely to a soft, white crystalline mass, consisting of hydrate of chloral, together with a small quantity of hydrochloric acid and undecomposed alcohol: *Crude Hydrate of Choral.* If a sample of the liquid, after being agitated with four times its volume of sulphuric acid, and set aside, does not in a few hours form a solid stratum of insoluble chloral above the oil of vitriol, the passage of the chlorine must be continued for a still longer time. The solidified crystalline mass is heated till it melts, briskly agitated with 4 to 6 times its bulk of sulphuric acid, which does not heat or blacken it; left at rest till the dehydrated chloral has risen to the top of the sulphuric acid, a result which may be accelerated by gentle heating; and the transparent, colourless film of chloral is immediately decanted by means of a pipette. If the sulphuric acid contains water, it is particularly necessary to decant as quickly as possible, before the chloral is thereby converted into insoluble chloral. Lastly, the chloral is distilled over lime which has been slaked and subsequently ignited, to remove hydrochloric acid, care being taken to keep the whole of the lime below the surface of the liquid, as it will otherwise decompose the vapour and become red-hot. In this manner the chloral is obtained tolerably pure; but it still contains traces of water and alcohol, which may be removed by repeated treatment with sulphuric acid, the chloral being each time rectified over lime. All these operations must be performed in well closed vessels. (Liebig.)

2. By distilling starch or sugar with hydrochloric acid and peroxide of manganese (Städeler). 1 pt. of starch, or grape-sugar, or common sugar, is gently heated with 7 pts. of commercial hydrochloric acid free from sulphurous acid and diluted with an equal volume of water, till the paste (formed when starch is used) has become fluid; the liquid, when cold, is introduced, together with 3 pts. of manganese and a small quantity of common salt (to fix the sulphuric acid produced from the sulphurous acid in the commercial hydrochloric acid) into a capacious flask, in which it is heated as quickly as possible to the boiling point; and the fire is then completely removed. The mass swells up, giving off a large quantity of carbonic acid, and continues to boil for some time by itself. As soon as the ebullition slackens, it must be kept up by fresh application of heat, and the distillate collected, as long as it becomes turbid when mixed with tolerably strong potash-ley (in consequence of separation of chloroform from the chloral). More hydrochloric acid is then repeatedly introduced into the flask by small portions, till the distillate no longer smells of chloral, or becomes turbid with potash. The watery distillate is carefully freed from the colourless oil-drops, heavier than water and smelling of chloroform, which are produced at the beginning of the distillation; and saturated with common salt, in order to raise its boiling point and retain the water. It is then redistilled, and the resulting distillate is freed from a sulphur-yellow very pungent oil, and distilled several times more with common salt, the oily drops being each time removed, in order to obtain aqueous chloral as concentrated as possible, and as free as possible from the yellow oil, which greatly impedes the purification.

The removal of this oil is facilitated by saturating the distillate, before each rectification, with chalk, which decomposes the oil, but does not attack the chloral. The concentrated solution of chloral is saturated with dry chloride of calcium, and distilled in an oil-bath at 120° C. Hydrate of chloral then passes over, as a colourless liquid, which solidifies in the receiver into a crystalline mass. The last portions of the distillate are contaminated with a brown oily substance. 1. From the hydrate of chloral thus obtained, the anhydrous chloral may be separated by distillation, and purified in the manner above described. (Städeler.)

Properties.—Chloral is a thin colourless oil, greasy to the touch, and making grease-spots on paper, which, however, soon disappear. Specific gravity = 1·502 at 18° C., 1·518 at 0°, 1·4903 at 22°. Boils at 94·4° (Liebig); at 98·6 when the barometer stands at 760 mm. (Kopp), and distils without decomposition. Vapour-density = 5·13. It has a peculiar pungent odour, and excites a copious flow of tears: its taste is greasy and slightly astringent. It acts very strongly on the skin, especially when its boiling vapour comes in contact therewith. It has no acid reaction, even when dissolved in water, and does not precipitate a solution of silver.

Mixed with a small quantity of water, it becomes heated and solidifies, forming a mass of crystals of *hydrate of choral*, $C^2HCl^3O.H^2O$: a larger quantity of water dissolves it, and the solution evaporated in vacuo deposits the hydrate of chloral in large rhombic laminæ. The hydrate volatilises gradually in the air, and distils without decomposition when heated. Its vapour-density is 2·76.

Chloral dissolves also in alcohol and in ether. It absorbs chlorine gas without further change, and readily dissolves iodine, bromine, sulphur, and phosphorus, especially when heated. The iodine-solution has a purple-colour.

Decompositions.—1. Chloral is under certain circumstances inclined to pass into an isomeric insoluble modification (p. 64).—2. Anhydrous chloral distils, for the most part unchanged, with *strong sulphuric acid;* but when hydrate of chloral is heated with that acid, part of the chloral distils over in the anhydrous state, while the rest is converted into *chloralide* (p. 61), with evolution of hydrochloric and sulphurous acids, and a trace of carbonic acid. This reaction serves for the detection of chloral in liquids. The liquid, concentrated by several distillations over chloride of calcium, is heated for some time, with six times its volume of strong sulphuric acid, to 125° C, and diluted, after cooling, with six measures of water. Chloralide then separates out mixed with carbonaceous particles; and the mixture washed, pressed between paper, exhausted with ether and evaporated, yields crystals of chloralide, which may be further purified by heating with sulphuric acid and recrystallisation from ether.—3. *Fuming nitric acid*, if ultimately aided by heat, converts chloral into trichloracetic acid: the same transformation is effected by a mixture of hydrochloric acid and chlorate of potassium.—4. *Anhydrous metallic oxides*, such as baryta, strontia, lime, cupric oxide, mercuric oxide, and peroxide of manganese, exert no action upon chloral, when that liquid is distilled over them. If, however, in the distillation of chloral over baryta, strontia or lime, a portion of the oxide is left dry, or if either of these substances is heated in chloral vapour merely to 100°, it becomes red-hot, and completely decomposes the choral, with evolution of carbonic oxide, and formation of a metallic chloride mixed with charcoal.—5. *Alkalis*, either in the form of solid hydrates or of aqueous solutions, decompose chloral readily at ordinary temperatures, with evolution of heat, converting it into formate of potassium and chloroform, and a portion of the latter compound is further decomposed, yielding formate and chloride of potassium:

$$\underset{\text{Chloral.}}{C^2HCl^3O} + KHO = \underset{\text{Formate of potassium.}}{CHKO^2} + \underset{\text{Chloroform.}}{CHCl^3}.$$

and $$CHCl^3 + 4KHO = CHKO^2 + 3KCl + 2H^2O.$$

—5. Vapour of chloral passed over *red-hot iron* yields carbonic oxide, and chloride of iron mixed with charcoal.—6. *Potassium*, in contact with chloral, eliminates hydrogen, and forms a resinous body from which water extracts potash and choride of potassium. —7. Chloral forms with *ammonia* a compound, which, like aldehyde-ammonia, reduces silver in the specular form, and from which sulphydric acid throws down a sulphuretted compound apparently analogous to thialdine (Städeler, Ann. Ch. Pharm. cvi. 253). — 8. *Sulphydric acid gas* passed through an aqueous solution of chloral separates a sparingly soluble crystalline compound, which is probably analogous to acetyl-mercaptan (p. 107), but decomposes much more easily, giving off sulphydric acid even during drying (Städeler). — 9. By boiling hydrate of chloral with *hydrocyanic* and *hydrochloric acid*, a syrupy acid is formed resembling lactic acid. These last three reactions indicate a close analogy between chloral and aldehyde, which is further strengthened by the fact that chloral forms crystalline compounds with acid sulphites of alkali-metal. (Städeler.)

Insoluble Chloral, Metachloral (Gm. viii. 205; Gerh. i. 671.) — Chloral is converted, under certain circumstances, into an isomeric modification insoluble in water. This change takes place spontaneously when chloral is preserved in a stoppered bottle, or when it is placed in contact with a quantity of water not sufficient to convert it into the hydrate. Metachloral thus prepared is pure, and has the same composition as chloral. It is also produced, mixed, however, with a little chloralide, by the action of sulphuric acid upon chloral. A layer of the crude hydrate of chloral obtained in the preparation of chloral from alcohol (p. 880), left in contact with strong sulphuric acid, solidifies in a few hours into a mass of insoluble chloral. Pure chloral in contact with six times its volume of strong sulphuric acid, undergoes the same transformation in the course of a night. The metachloral thus obtained may be purified from chloralide by pulverising, and washing it, first with water and then with alcohol.

Metachloral is a white powder, greasy to the touch, and having a faint aromatic odour. It volatilises slowly in the air or in vacuo. It is insoluble in water, alcohol, and ether. When perfectly dry, it is reconverted by heat into soluble chloral, at 180°C, according to Kolbe, above 200° according to Regnault. Heated with sulphuric acid, it partly distils over as soluble chloral, but a considerable portion is decomposed, with formation of chloralide, and evolution of hydrochloric and sulphurous acids. By fuming nitric acid, metachloral is, like chloral, converted into trichloracetic acid; but it is not attacked by a mixture of hydrochloric acid and chlorate of potassium. With solutions of the caustic alkalis, it behaves like ordinary chloral, yielding an alkaline formate and chloroform; but the quantity of the latter is less as the alkali is more concentrated.

CHLORAL, AMYLIC. See CHLORAMYLAL.

CHLORAL, MESITIC. This name was applied by Kane (Pogg. Ann. xliv. 473) to a pungent vesicating liquid of specific gravity 1·33, and boiling at 71° C., which is obtained by passing dry chlorine into acetone. Kane's analysis gives 56·8 per cent. chlorine; Liebig found only 52·6 per cent. It is probably a mixture containing two or more of the chloracetones (p. 29).

CHLORAL, PROPIONIC. *Hydride of Pentachloropropione*, $C^3Cl^5O^2.H$. This body is found amongst the products obtained by distilling starch with a mixture of hydrochloric acid and peroxide of manganese. On saturating the acid distillate with chalk or carbonate of sodium, and rectifying over a small quantity of chloride of calcium, the propionic chloral passes over among the first portions, together with an oil. To remove the latter, the rectified distillate is agitated several times with ice-cold water, and the cold saturated solution is decanted and heated, the propionic chloral then separating in heavy drops having a faint yellow colour. By diffusing these drops through a small quantity of water, and exposing them to a temperature of 0° C., colourless tables are obtained, which may be purified from adhering oil by pressure between bibulous paper. They consist of a hydrate containing 4 at. water: $C^3HCl^5O^2.4H^2O$. (Städeler, Handw. d. Chem. Suppl. ii. 796.)

CHLORALBIN. $C^6H^6Cl^2$.—A crystalline substance contained in trichlorophenic acid prepared by passing chlorine through coal-tar. It is separated by treating the crude acid with ammonia and alcohol, or better with ether, whereupon the chloralbin remains in very white needles; it may be further purified by dissolving it in boiling ether. It is but sparingly soluble in boiling alcohol, and insoluble in alkalis. It boils at 190° C., and crystallises on cooling in fern-like tufts. At a higher temperature, it sublimes without alteration and crystallises in needles. It is not attacked by hot nitric or sulphuric acid. (Laurent, Rev. scient. vi. 72.)

CHLORALDEHYDES. These compounds are aldehydes in which the hydrogen is more or less replaced by chlorine, and may be regarded as derived from the corresponding acids by the substitution of 1 or more at. chlorine for an equivalent quantity of peroxide of hydrogen HO, thus:

	Chloraldehydes.	Acids.
Acetic	$C^2H^3O.Cl$	$C^2H^3O.HO$
Trichloracetic . . .	$C^2Cl^3O.Cl$	$C^2Cl^3O.HO$
Nitric	$NO^2.Cl$	$NO^2.HO$
Sulphuric	$(SO^2)''.Cl^2$	$(SO^2)''.(HO)^2$
Phosphoric	$(PO)'''.Cl^3$	$(PO)'''.(HO)^3$

The chloraldehydes are a more numerous class of compounds than the aldehydes themselves, including many compounds usually denominated oxychlorides, *e. g.* oxychloride of phosphorus. They bear to their corresponding acids the same relation that metallic chlorides bear to metallic hydrates.

The term chloraldehyde is also specially applied to the second compound in the above list, viz:

Chloride of Trichloracetyl or *Perchlorinated Acetic Aldehyde*, $C^2Cl^4O = C^2Cl^3O.Cl$.—This body, discovered by Malaguti (Ann. Ch. Phys. i. [2] xvi. 5); Gm. ix. 218; Gerh. i. 756), is a constant product of the action of heat on the perchlorinated ethylic (vinic) ethers. Thus:

$$\underset{\text{Perchlor. oxide of ethyl.}}{C^4Cl^{10}O} = C^7Cl^4O + \underset{\text{Sesquichloride of carbon.}}{C^2Cl^6}.$$

$$\underset{\text{Perchlor. formate of ethyl.}}{C^3Cl^6O^2} = C^2Cl^4O + \underset{\text{Oxychloride of carbon.}}{COCl^2}.$$

$$\underset{\text{Perchlor. acetate of ethyl.}}{C^4Cl^8O^2} = 2C^2Cl^4O$$

$$\underset{\text{Perchlor. carbonate of ethyl.}}{C^5Cl^{10}O^3} = C^2Cl^4O + C^2Cl^6 + CO^2.$$

$$\underset{\text{Perchlor. oxalate of ethyl.}}{C^6Cl^{10}O^4} = 2C^2Cl^4O + COCl^2 + CO.$$

It is best prepared from perchlorinated oxide of ethyl, $C^4Cl^{10}O$ (the product obtained by the continued action of chlorine in sunshine, on anhydrous ether). This compound is resolved at 300° C. into chloride of trichloracetyl and trichloride of carbon; and by subjecting the mixture to repeated fractional distillation, the trichloride of carbon is left behind, and the chloride of trichloracetyl is obtained pure. The rectification must be continued till the distillate no longer shows any turbidity when mixed with water.

Chloraldehyde is a transparent, colourless liquid, of specific gravity 1·603 at 18° C. Boiling point 118°. Vapour-density 6·32 (calc. 2 vol. 6·295). It gives off excessively pungent vapours on exposure to the air, and when placed on the tongue, first excites a sensation of dryness, then forms a white spot, and ultimately exerts a caustic action. It reddens litmus after a few seconds.

It sinks in water, and gradually dissolves, forming a clear solution of hydrochloric and trichloracetic acids: the same decomposition is produced by aqueous solutions of the fixed alkalis:

$$C^2Cl^3O.Cl + H^2O = HCl + C^2Cl^3O.H.O.$$

When a small quantity of alcohol is poured upon it, great heat is evolved, and the whole is quickly volatilised; but if the chloraldehyde be slowly added to an excess of alcohol, gradual decomposition takes place, attended with but little rise of temperature, the products being hydrochloric acid and trichloracetate of ethyl:

$$C^2Cl^3O.Cl + C^2H^5.H.O = HCl + C^2Cl^3O.C^2H^5.O$$

With ammonia it forms trichloracetamide (p. 22);

$$C^2Cl^3O.Cl + 2NH^3 = N.H^2.C^2Cl^3O + NH^4Cl,$$

and with phosphoretted hydrogen, PH^3, the analogous compound, chloracetyphide, $P.H^2.C^2Cl^3O$ (p. 879).

CHLORALIDE. $C^5H^2Cl^6O^3$. (Städeler, Ann. Ch. Pharm. lxi. 104.—Kekulé, *ibid.* cv. 293.)—A crystalline compound obtained by the action of sulphuric acid upon hydrate of chloral. To prepare it, hydrate of chloral is gently heated with 4 to 6 times its volume of strong sulphuric acid, the mixture being well shaken, and then distilled at a heat between 120° and 130° C., as long as unaltered choral continues to pass over. This choral is reconverted into hydrate by addition of a little water, then poured back, and the distillation is repeated till the greater part of the chloral is decomposed. The sulphuric acid is then found to be covered with a colourless oily liquid, which solidifies on cooling into a white crystalline crust. This mass is broken up, the sulphuric acid is drained off, and the crystals are washed with water, till the wash-water no longer reddens litmus; they are then dried between bibulous paper, and dissolved in ether, and the ethereal solution is mixed with ⅓ its volume of alcohol. The chloralide then separates as the ether evaporates, in well-defined crystals, which must be crystallised several times from a mixture of alcohol and ether, in order to free them from an oily matter which adheres to them:—According to Kekulé (Ann. Ch. Pharm. cv. 293), a purer and more abundant product is obtained by the action of fuming sulphuric acid on hydrate of chloral. When chloral which has been once distilled over ordinary sulphuric acid, is mixed with an equal volume of acid, a large quantity of hydrochloric acid is evolved, and about one-third of the chloral is converted into chloralide. Carbonic oxide is also given off abundantly, together with a very small quantity of carbonic anhydride; sulphurous anhydride occurs only towards the end of the process. The oily distillate solidifies on cooling in a crystalline mass, which may be purified by recrystallisation from boiling alcohol.

Kekulé explains the formation of chloralide and the accompanying products by the following equation:—

$$3C^2HCl^3O + H^2O = C^5H^2Cl^6O^3 + 3HCl + CO.$$

Städeler, on the other hand, considers it improbable that the conversion of the chloral into chloralide can be due to the action of water, inasmuch as fuming sulphuric acid seems to act better than ordinary sulphuric acid. He supposes that a triple molecule of chloral (insoluble chloral) splits up into chloralide and chloroform, according to the equation:

$$3C^2HCl^3O = C^5H^2Cl^6O^3 + CHCl^3,$$

and attributes the evolution of carbonic oxide observed by Kekulé, to the resolution of a molecule of chloral into this gas and chloroform:

$$C^2HCl^3O = CO + CHCl^3.$$

Chloralide is insoluble in water, and likewise in sulphuric acid. It dissolves sparingly in cold alcohol, but easily in boiling alcohol and in ether. From a hot saturated alcoholic solution, it is deposited in very delicate white needles; from a mixture of alcohol and ether, in stellate groups of rectangular prisms belonging to the monoclinic system, with oblique terminal faces, and generally having their lateral edges truncated. They are transparent and colourless, with a glassy lustre, and cleave with facility in a direction parallel to the prismatic faces. Chloralide melts between 112° and 114° C. to an oily liquid, emitting at the same time an odour like that of chloral: it solidifies at 108° (Kekulé). Chloralide burns at 200° (Städeler); at 260° (Kekulé) with a bright flame, green at the edges.

The alcoholic solution of chloralide does not precipitate nitrate of silver, but on adding a drop of ammonia, a precipitate is immediately formed, consisting of chloride of silver. Chloralide immersed in aqueous potash, is resolved into chloroform and formate of potassium; but if alcoholic solutions are used, the only products are formate and chloride of potassium, these compounds being in fact produced by the action of alcoholic potash upon chloroform.

The composition of chloralide has been variously stated by different chemists. Städeler, who discovered it, assigned to it the formula $C^5H^2Cl^6O^3$, which is confirmed by the recent experiments of Kekulé. Gerhardt (*Traité*, i. 672) proposed the formula $C^8H^3Cl^7O^4$; Gmelin (*Handbook*. ix. 207) gave $C^8H^4Cl^{10}O^8$, and in the *Handwörterbuch der Chemie*, 2^te Aufl. i. 112, the formula $C^4HCl^3O^2$ is assigned to this compound.

The following table exhibits the calculated composition of chloralide, according to the preceding formulæ, as compared with the results of analysis:

	Calculation according to:				*Analysis:*	
	Städeler.	Gerhardt.	Gmelin.	Handw.	Städeler.	Kekulé.
	$C^5H^2Cl^6O^3$	$C^6H^3Cl^7O^4$	$C^8H^4Cl^{10}O^5$	$C^4HCl^3O^2$	*mean*	*mean*
C . . .	18·61	18·50	17·98	18·55	18·64	18·64
H . . .	0·62	0·77	0·39	0·75	0·77	0·72

CHLORALOÏL. A product of the action of chlorine upon aloin (p. 148).

CHLORALURIC ACID. An acid produced, together with other substances, by the action of chlorous acid on uric acid. It crystallises in nacreous laminæ; forms crystallisable salts with barium and lead, and a curdy precipitate with silver-salts. It gave by analysis 27·3 per cent. C, 3·8 H, 28·1 N, and 11·4 Cl, numbers which are approximately represented by the formula $C^{14}H^{22}N^{12}Cl^2O^{11}$. (Schiel, Ann. Ch. Pharm. cxii. 78.)

CHLORAMYLAL. C^5H^9ClO (?) — A heavy liquid produced by the action of chlorine upon amylic alcohol (*q. v.*)

CHLORANIL. Syn. with PERCHLOROQUINONE, $C^6Cl^4O^2$. (See QUINONE.)

CHLORANILAMIC ACID. Syn. with DICHLOROQUINONAMIC ACID. (See QUINONIC ACID).

CHLORANILAMIDE. Syn. with DICHLOROQUINONAMIDE. (See QUINONIC ACID.)

CHLORANILAMMONE. Syn. with DICHLOROQUINONAMATE OF AMMONIUM.

CHLORANILIC ACID. Syn. with DICHLOROQUINONIC ACID. (See QUINONIC ACID.)

CHLORANILINE. Syn. with CHLOROPHENYLAMINE. (See PHENYLAMINE.)

CHLORANISIC ACID. See ANISIC ACID (p. 302).

CHLORASTROLITE. A mineral found on the shores of Isle Royale, Lake Superior, in small rounded water-worn pebbles which have come from the trap. It has a finely radiated or stellate structure, light bluish-green colour, and pearly lustre slightly chatoyant on the rounded sides. Specific gravity 3·180. Hardness 5·5—6. Analyses by Whitney:

SiO^2	Al^4O^6	Fe^4O^3	Ca^2O	Na^2O	K^2O	H^2O
36·99	25·49	6·48	19·90	3·70	0·40	7·22 = 101·18
37·41	24·25	6·76	21·68	4·88		5·77 = 100·25

These numbers lead to the formula —

$$3\left[\left(\begin{matrix}\frac{6}{7}Ca^2O\\ \frac{1}{7}Na^2O\end{matrix}\right)^2.SiO^2\right] + 2\left[\left(\begin{matrix}\frac{6}{7}Al^4O^6\\ \frac{1}{7}Fe^4O^3\end{matrix}\right)^2.3SiO^2\right] + 6H^2O.$$

which, if M = Ca, Na and $m = \frac{2}{3}$ (Al, Fe), may be reduced to that of an orthosilicate, $(M^4m^6)Si^3O^{12} + 2\,aq.$

The mineral gives off water when heated, and melts with intumescence before the blowpipe to a greyish blebby glass. With borax it forms a transparent glass tinged with iron; blue with cobalt solution. Dissolves in hydrochloric acid, with separation of flocculent silica. (Dana, ii. 315.)

CHLORATES. Chloric acid, $HClO^3$, is monobasic and forms but one class of salts, having the general formula $MClO^3$ or $M^2O.Cl^2O^5$. They are all soluble in water, and are resolved by heat into oxygen and a metallic chloride. (See CHLORIC ACID under CHLORINE, p. 910.)

CHLORATE OF ALUMINIUM is a deliquescent salt obtained by precipitating a solution of silico-fluoride of aluminium with an equivalent quantity of potassium, and evaporating the filtrate. (Berzelius.)

CHLORATE OF AMMONIUM is obtained by adding ammonia or the carbonate to chloric acid; by precipitating an earthy chlorate with carbonate of ammonium; or by adding finely divided chlorate of potassium by small portions to a solution of silico-fluoride of ammonium, and filtering. It crystallises in slender needles, has a pungent taste, explodes when heated, and sometimes, according to Mitscherlich, even at ordinary temperatures. Dissolves easily in water and in alcohol.

CHLORATE OF BARIUM, $BaClO^3$.—Prepared: 1. By saturating aqueous chloric acid with baryta-water or carbonate of barium. *a.* A hot solution of chlorate of potassium is precipitated with hydrofluosilicic acid in slight excess, and the filtrate is saturated with carbonate of barium, whereupon chlorate of barium dissolves, and a small quantity of silico-fluoride of barium remains behind. The filtered solution yields crystals of the chlorate by evaporation (Wheeler, Ann. Ch. Phys. [2] vii. 74). *b.* A solution of 27 pts. chlorate of sodium in 54 pts. water is mixed with a solution of 38 pts. tartaric acid in 38 pts. water; the mixture is thrown into double the quantity of absolute alcohol; and the liquid, after standing 24 hours, is filtered from the crystallised tartrate of sodium, then saturated with carbonate of barium, &c. (Duflos, N. Br. Arch. xxiii. 306.) *c.* Equivalent quantities of chlorate of potassium and acid tartrate of ammonium (122·6 pts. of the former to 167 of the latter) are dissolved in the smallest possible quantity of boiling water; the liquid, after the acid tartrate of potassium has crystallised out, is mixed with an equal quantity of alcohol; the filtrate decomposed by boiling with carbonate of barium, &c. (L. Thompson, Jahresber. f. Chem. 1847—8, p. 381.)

2. By passing chlorine into hot water in which baryta is partly suspended, partly dissolved. Chloride and chlorate of barium are then formed, the greater part of the chloride is suffered to crystallise out, and the rest is removed by adding phosphate of silver to the solution, in the exact quantity required. (Chenevix, Vauquelin, *Gmelin's Handbook*, ii. 161.)

Chlorate of barium forms hydrated prismatic crystals, $2BaClO^3 + H^2O$, belonging to the monoclinic system. Ratio of orthodiagonal, clinodiagonal, and principal axis = 0·882 : 1 : 1·07. Inclination of axes = 85° 30'; $\infty P : \infty P$ in the orthodiagonal section = 97°; $[P\infty] : [P\infty]$, in the clinodiagonal section = 79° 10'. Ordinary combination $\infty P . [P\infty] . -P\infty$; also without $-P\infty$; also with $\infty P\infty$ (Kopp, *Krystallographie*, p. 304), and less frequently with 0P (Rammelsberg, Pogg. Ann. xc. 16). The crystals are transparent and colourless, give off their water (4·72 per cent.) at 120° C., oxygen at 250°, and melt at a temperature above 400° (Wächter, Ann. Ch. Pharm. lii. 231; Souchay, *ibid.* cii. 381). The salt detonates powerfully with combustible bodies; produces a green flame when heated with sulphur (Duflos); and emits a bright flashing light with strong sulphuric acid (Chenevix). It dissolves easily in water, but is insoluble in alcohol. The anhydrous salt dissolves in 4·38 pts. of water at 0° C., in 2·70 pts. at 20°, in 1·92 pts. at 40°, in 1·29 pts. at 60°, in 1·02 pts. at 80°, and in 0·79 pts. at 100° (Kremers, Jaheresber. d. Chem. 1856, p. 274.) According to Hutstein (Arch. Pharm. [2] lxxvii. 137) it emits light on crystallising.

Chlorate of Calcium, $CaClO^3 + H^2O$.—Prepared like the barium-salt. Crystallises in deliquescent rhomboïdal prisms, easily soluble in water and alcohol. They contain 16·5 p.c. water, melt in their water of crystallisation when gently heated, and decompose at a higher temperature. (Gm. iii. 212.)

Chlorate of Cobalt, $CoClO^3 + 3H^2O$.—Crystallises in cubo-octahedrons. Decomposed by ignition into chlorine, oxygen, and a residue containing oxide and chloride of cobalt. (Wächter, Ann. Ch. Pharm lii. 233.)

Chlorate of Copper, $CuClO^3 + 3H^2O$.—A solution of cupric oxide in chloric acid yields green deliquescent octahedrons having a slight acid reaction, and soluble in alcohol. At 100° C. it gives off a few gas-bubbles, and at 260° suffers further decomposition, leaving a residue which is insoluble in water but soluble in acids, and appears to consist of a basic chlorate, inasmuch as its solution in nitric acid gives no precipitate with silver-salts (Wächter, *loc. cit.*) Cupric chlorate detonates with bright green flame on glowing coals, and is much used in pyrotechny for the production of green fire.

Chlorate of Lead, $2PbClO^3 + H^2O$.—Rhomboïdal prisms, which become dull and opaque by exposure to the air; soluble in water and alcohol but not deliquescent. When heated, they leave oxychloride of lead containing Pb^6Cl^4O. (Wächter.)

Chlorate of Lithium, $2LiClO^3 + H^2O$.—Radiated, very deliquescent mass, melting at 0° C., and giving off water at 140°, together with oxygen and small quantities of chlorine. Very soluble in alcohol. (Wächter.)

Chlorate of Magnesium, $MgClO^3 + 3H^2O$.—Crystalline crust, easily soluble in alcohol, melting at 40° C., and giving off its water at 120°; (Chenevix, Wächter.)

Chlorate of Manganese.—Colourless, known only in solution.

Chlorates of Mercury.—The *mercuric* salt is obtained by dissolving mercuric oxide in warm chloric acid (Vauquelin), or by heating mercuric oxide with successive portions of chlorine-water, filtering from mercuric oxychloride, and concentrating the filtrate; mercuric chloride then crystallises out, while the chlorate remains in solution (Braamcamp and Siqueira.) Mercuric chlorate forms small deliquescent needles, which redden litmus, taste like the chloride, and are resolved by heat into oxygen gas, mercurous chloride, calomel, and metallic mercury. The salt does not deflagrate on red-hot coals, but sets fire to sulphide of antimony at ordinary temperatures. (Gm. vi. 62.)

Mercurous Chlorate, $Hg^2O.ClO^5$ or $HhgClO^3$. — A solution of mercurous oxide in chloric acid yields the salt in beautiful prismatic crystals, which dissolve in water and in alcohol, and are resolved by heat into oxygen, metallic mercury, and calomel. (Wächter.)

CHLORATE OF NICKEL, $NiClO^3 + 3H^2O$, crystallises in regular octahedrons of a deep green colour, deliquescent and soluble in alcohol. When heated, they give off oxygen and chlorine, and leave a mixture of chloride and oxide of nickel; at a very strong red heat, however, nothing but oxide remains behind. (Wächter.)

CHLORATE OF POTASSIUM, $KClO^3$, or $KO.ClO^5$.—This salt is an important article of manufacture, being used in the preparation of lucifer matches and for other purposes in the arts. It is prepared, either by passing chlorine into solution of potash or carbonate of potassium, whereby chlorate and chloride of potassium are formed, which are separated by crystallisation, the chlorate being much the less soluble of the two; or by decomposing chlorate of calcium with sulphate or chloride of potassium.

1. A solution of 1 pt. hydrate of potassium in 3 pts. water is saturated with chlorine gas, whereby chloride and hypochlorite of potassium are produced, the liquid acquiring strong bleaching properties:

$$2KHO + Cl^2 = KClO + KCl + H^2O.$$

The liquid is then left to itself for a day, or heated for some time to the boiling point, whereby the hypochlorite is completely resolved into chloride and chlorate:

$$3KClO = 2KCl + KClO^3.$$

The ultimate result is to convert 6 at. hydrate of potassium, by the action of 6 at. chlorine, into 1 at. $KClO^3$ and 5 at. KCl. It has been found that if a solution of potash either stronger or weaker than that above mentioned be used, part of the chlorate produced is decomposed into free oxygen and chloride of potassium.

The solution, when left to itself, deposits the greater part of the chlorate of potassium in crystals, which may be purified from adhering chloride by recrystallisation. The mother-liquor yields by concentration an additional quantity of chlorate, which, however, is more contaminated with chloride, and requires a greater number of crystallisations to purify it. The test of purity is that the solution is not clouded by a drop of nitrate of silver.

Carbonate of potassium may be used for the preparation instead of caustic potash. In that case a considerable quantity of acid carbonate of potassium is formed in the early stage of the process, and crystallises on the sides of the vessels; but on continuing the passage of the chlorine, this salt is decomposed, with evolution of carbonic acid, the ultimate products being chlorate and chloride of potassium as before.

Carbonate of potassium may also be used in the solid form, being laid on shelves or trays in a chamber into which chlorine gas is introduced, just as in the manufacture of bleaching powder. When the absorption of the chlorine is complete, the product is dissolved in water, and the chlorate crystallises out, as above described.

2. Hypochlorite of calcium, or bleaching powder, the so-called "chloride of lime" is made into a "cream" with water, and submitted to continuous boiling or evaporation to dryness, whereby it is resolved into a mixture of chlorate and chloride of calcium (p. 910), a change the completion of which is indicated by the loss of bleaching properties in the mass. The residue, after evaporation, is treated with water, and chloride or sulphate of potassium is added, whereby the chlorate of calcium is decomposed, with production of chlorate of potassium and chloride or sulphate of calcium. The chlorate, amounting to about $\frac{1}{10}$ of the weight of chloride of lime employed, is separated from sulphate of calcium by the insolubility of the latter, or from chloride of calcium by crystallisation.

The process now generally employed consists in a modification of the last, in which the chloride of lime is formed in the same operation as the chlorate itself, instead of starting from a previously manufactured bleaching powder. Excess of chlorine is passed into a mixture of 300 pts. caustic lime and 154 of chloride of potassium with 100 water, the operation being performed in close leaden tanks, heated by steam and provided with agitators. A man-lid, through which the tank can be cleansed or repaired, and one or two wide tubes descending nearly to the bottom of the vessel, through which materials can be introduced, complete the arrangement. During the action, the temperature rises to about 200° F. After the completion of this operation, the liquid is filtered and evaporated nearly to dryness by steam heat; and the resulting mass is redissolved in hot water and set to crystallise.

The whole of the chloride of calcium remains in the mother-liquors, and the crystals of chlorate are rendered fit for the market by slight washing and draining. The reaction upon which this operation depends is represented by the following equation:

$$KCl + 3Ca^2O + 6Cl = KClO^3 + 6CaCl.$$

In this process, 154 pts. KCl give more than 200 pts. $KClO^3$, while, by the method of direct saturation, 115 pts. caustic potash yield only 30 pts. of that salt; at the same time, no by-product is formed except chloride of calcium. The crystallisable mother-liquors of this manufacture consist, within 1 or 2 per cent., entirely of this salt, and may be decomposed either by an addition of sulphate of potassium or of carbonate of sodium. In the former case, sulphate of calcium is precipitated, available in the manufacture of paper, while chloride of potassium remains in solution, and may be recovered by evaporation, to be employed in the preparation of fresh portions of chlorate: in the latter, carbonate of calcium, the "creta præcipitata" of the druggist, is precipitated, and is largely employed by the pharmaceutist and the perfumer. Nearly the whole of the waste liquors of the English manufacturer are converted into the latter product.

Carbonate instead of chloride of potassium may also be mixed with the quick lime: in that case, on treating the mixture with water, after it has been exposed to the action of chlorine, the whole of the lime remains as carbonate, while chloride and chlorate of potassium are dissolved. (Gm. iii. 59, *Ure's Dictionary of Arts, Manufactures and Mines*, i. 66.)

Properties.—Chlorate of potassium crystallises in anhydrous six-sided laminæ, more rarely in needles. The crystals belong to the monoclinic system. Ratio of orthodiagonal, clinodiagonal, and principal axis = 1·360 : 1 : 0·804. Inclination of axes = 70° 11′. Ordinary combination $\infty P . 0P . +P . +2P\infty$; also twin-crystals. Cleavage parallel to ∞P and $0P$.

Chlorate of potassium is but slightly soluble in cold water. The quantities dissolved by 100 pts. of water at different temperatures, as determined by Gay-Lussac, are given in the following table:

at 0° C.	3·3 pts.	at 49·06° C.	18·98 pts.
15·37°	6·03 „	74·39°	85·40 „
24·43°	8·44 „	104·78°	60·24 „
35·02°	12·05 „		

It is insoluble in absolute alcohol.

Chlorate of potassium is permanent in the air at ordinary temperatures, but is easily decomposed by heat, being at first resolved into chloride and perchlorate of potassium, with a small quantity of free oxygen: $2KClO^3 = KCl + KClO^4 + O^2$, while at a higher temperature the whole of the oxygen is given off (39·15 per cent. of its weight in all), and chloride of potassium remains.

The decomposition is greatly facilitated by mixing the chlorate with peroxide of manganese or oxide of copper, the whole of the oxygen of the chlorate being then given off at a low red heat without previous formation of perchlorate: such a mixture is very convenient for the evolution of oxygen. The metallic oxide does not undergo any alteration, appearing to act merely by dividing the particles of the chlorate and preventing them from fusing into a mass.

Chlorate of potassium is a powerful oxidising agent, and detonates violently when mixed with certain combustible bodies and struck or heated. Triturated in a mortar with *flowers of sulphur*, it produces a series of sharp detonations. A mixture of the salt with *sulphide of antimony* takes fire when triturated, sometimes with explosion. A small quantity of the chlorate mixed with *phosphorus* and struck with a hammer detonates with a loud report. These combustions are attended with great danger when large quantities are used.

Chlorate of potassium is decomposed by acids, with evolution of peroxide of chlorine, chlorous acid, or hypochlorous acid. With *strong sulphuric acid*, it is resolved into peroxide of chlorine, perchlorate, and acid sulphate of potassium:

$$3KClO^3 + 2H^2SO^4 = 2ClO^2 + KClO^4 + 2KHSO^4 + H^2O$$

The decomposition is attended with violent decrepitation, and sometimes with a flashing light; combustible substances, such as sulphur, phosphorus, metallic sulphides, arsenic, sugar, gum, resin, &c., are inflamed by the peroxide of chlorine evolved. A finely-divided mixture of chlorate of potassium and excess of crystallised *oxalic acid* heated to about 70° C. gives off peroxide of chlorine mixed with carbonic anhydride, while chloride and acid oxalate of potassium remain (Calvert and Davies, Chem.

Soc. Qu. J. xi. 193). The reaction probably takes place in the manner represented by the equation:

$$3KClO^3 + 6C^2H^2O^4 = 2C^2KHO^4 + KCl + 2ClO^2 + 8CO^2 + 5H^2O.$$

Chlorate of potassium boiled with *strong nitric acid* yields nitrate and perchlorate of potassium, with evolution of chlorine and oxygen, but no peroxide of chlorine. (Penny, J. pr. Chem. xxiii. 296):

$$8KClO^3 + 6HNO^3 = 6KNO^3 + 2KClO^4 + Cl^6 + O^{13} + 3H^2O.$$

Dilute nitric acid free from nitrous acid does not act on chlorate of potassium, even when boiled; but if it contains *nitrous acid*, or if any reducing agent is present, such as tartaric acid, or arsenious acid, a lower oxide of chlorine is produced. If the temperature be kept below 5° C. the chief product is chlorous acid, $HClO^2$, the nitrous acid being at the same time reconverted into nitric acid: $HNO^2 + HClO^3 = HNO^3 + HClO^2$ (Millon, Ann. Ch. Pharm. xlvi. 298). Chlorate of potassium heated with hydrochloric acid, yields chloride of potassium, and gives off a mixture of peroxide of chlorine and free chlorine, called *euchlorine*, having the proportional composition of hypochlorous anhydride ($ClO^2 + Cl^3 = 2Cl^2O$). The reaction is:

$$4KClO^3 + 12HCl = 4KCl + 6H^2O + 3ClO^2 + Cl^9.$$

A mixture of chlorate of potassium and hydrochloric acid is much used as an oxidising agent, *e. g.* for the destruction of organic matter in toxicological investigations.

Chlorate of potassium heated with *pentachloride of phosphorus*, gives off a deep yellow gas which does not explode when heated, and when passed into dilute potash-ley, forms chloride, chlorate, and hypochlorite of potassium (H. Schiff, Ann. Ch. Pharm. cvi. 116).—Chlorate of potassium distilled with *iodine*, gives off a chloride of iodine, while chloride and iodate of potassium remain mixed with the excess of chlorate (Wöhler):

$$KClO^3 + I + I^x = KIO^3 + I^xCl.$$

Iodic acid added to solution of chlorate of potassium, forms crystals of neutral or acid iodate of potassium, while free chloric acid remains in solution. (Serullas.)

Chlorate of potassium is extensively used in the manufacture of lucifer matches and fire-works. Lucifer matches which take fire by friction, are tipped with a mixture of chlorate of potassium, phosphorus, and glue or gum.

Mixtures for producing fires of various colours, are composed as follows:

Red fire.		Green fire.		Purple fire.	
Nitrate of strontium	40 pts.	Nitrate of barium	77 pts.	Oxide of copper	12 pts.
Chlorate of potassium	6 „	Chlor. of potassium	8 „	Chlor. potassium	30 „
Fine charcoal	2 „	Fine charcoal	3 „		—
Sulphur	13 „	Sulphur	13 „	Sulphur	12 „

The following composition is applied to the interior of percussion caps, in quantities varying from 0·2 to 0·3 of a grain. Chlorate of potassium 26 pts., nitre 30, fulminate of mercury 12, sulphur 17, ground glass 14, gum 1 (= 100).

Chlorate of potassium is now extensively used as an oxidising agent in heightening the intensity of *steam-colours* on printed goods. It is of constant use in the laboratory as a source of oxygen, and is employed in medicine in the treatment of irritation of the mucous membranes. For the manufacture of gunpowder it is not well adapted, as the powder made with it, produces a very violent explosive force within a small space only, and bursts the gun instead of propelling the ball.

Chlorate of Silver, $AgClO^3$.—Obtained by dissolving oxide of silver in chloric acid, or by passing chlorine through water in which the oxide is suspended, filtering from chloride of silver, and evaporating. It crystallises in white opaque four-sided prisms, with oblique terminal faces (Vauquelin), of specific gravity 4·430 (Schröder); tastes like the nitrate. It deflagrates brightly on hot coals, and when mixed with sulphur, detonates violently on the slightest pressure. Hydrochloric, nitric, and acetic acid, convert it into chloride, with evolution of oxygen.

Chlorate of Sodium, $NaClO^3$.—This salt may be prepared by the action of chlorine on solution of soda; but it is difficult to separate from the chloride formed at the same time; the separation might, however, be effected by alcohol, which dissolves the chlorate much more easily than the chloride. The salt is likewise obtained by decomposing chlorate of potassium with silico-fluoride or acid tartrate of sodium, or chlorate of ammonium by carbonate of sodium (Wittstein). It might also be prepared by decomposing chlorate of calcium with carbonate of sodium.

Chlorate of sodium crystallises in regular tetrahedrons, modified by the faces of the opposite tetrahedron, also of the cube and rhomboïdal dodecahedron: the crystals are isomorphous with those of bromate of sodium. They dissolve in 3 times their weight of cold water, and in a smaller quantity of boiling water; also in 34 pts. of 83 per cent. alcohol at 16° C. and in a smaller quantity of hot alcohol.

CHLORATE OF STRONTIUM, $SrClO^3$.—Prepared like the barium-salt. Crystallises in deliquescent needles, or, according to Wächter, in large pyramidal crystals. It decomposes at the same temperature as the barium-salt, and deflagrates with purple flame on glowing coals.

CHLORATE OF URANIUM.—Protoxide of uranium dissolves in chloric acid, forming a green solution, which decomposes spontaneously, with evolution of chlorine and formation of uranic chloride. (Rammelsberg.)

CHLORATE OF ZINC, $ZnClO^3 + 3H^2O$, is obtained by dissolving carbonate of zinc or metallic zinc in chloric acid, chloride of zinc being also formed in the latter case; also by passing gaseous fluoride of silicon into water in which carbonate of zinc is suspended, and boiling the filtered liquid with chlorate of potassium. It crystallises, apparently, in octahedrons, has a very rough taste, and is soluble in water and alcohol.

CHLORETHERAL. Syn. with MONOCHLORETHYLIC ETHER. See ETHYL, OXIDE OF (ii. 643).

CHLORHYDRIC or **HYDROCHLORIC ACID.** HCl.—This gas is the only known compound of chlorine and hydrogen. Its solution in water has been used from very early times, and has received the names of *spirit of salt, muriatic acid, hydrochloric acid*, and *chlorhydric acid*. The gas was discovered by Priestley in 1772.

Natural Sources.—Hydrochloric acid gas is evolved from volcanos in eruption, and the acid solution is sometimes found in crevices on their slopes. It exists also, to the amount of 1 or 2 pts. in a thousand, in certain rivers of South America which have their source in volcanic formations.

Formation and Preparation.—1. Hydrochloric acid is produced by the direct union of chlorine and hydrogen. A mixture of the two gases in equal volumes, explodes violently if a burning body is introduced into it, or an electric spark passed through it, or if it be exposed to direct sunshine (Gm. ii. 319). No combination takes place in the dark, but if the mixture be exposed to diffused daylight, the gases combine gradually. Thus, if two bottles of exactly equal capacity and fitted to one another by grinding, are filled by displacement with chlorine and hydrogen respectively, then adapted to each other by their mouths, the chlorine-vessel being placed uppermost, and set aside for some hours in a light situation, but not in direct sunshine, the green colour of the chlorine will gradually disappear almost entirely, and a few minutes' exposure to sunshine will complete the combination. If the two bottles be then separated under mercury, each will be found full of hydrochloric acid gas, no gas escaping and no rising of the mercury taking place in either bottle, showing that the chlorine and hydrogen have combined without expansion or contraction. If a jet of water tinged with blue litmus be thrown up into either of the bottles, the gas will be rapidly and completely absorbed, while the litmus solution will assume a bright red colour. Any bleaching of the litmus would indicate free chlorine; any unabsorbed gas, the presence of free hydrogen; in this manner, an excess of either gas in the original mixture may be detected.

2. Hydrochloric acid gas is usually prepared by the action of sulphuric acid on fused chloride of sodium. There is at first a copious effervescence, which, after some time, it may be necessary to revive by the application of a gentle heat. The reaction is:

$$NaCl + H^2SO^4 = NaHSO^4 + HCl.$$

The gas must be collected over the mercurial trough, as it is rapidly absorbed by water.

3. Hydrochloric acid may also be produced by the action of water on certain chlorides. The two chlorides of phosphorus are decomposed immediately and completely by mixture with an excess of water, with formation of phosphorous and phosphoric acid respectively, thus:

$$PCl^3 + 3H^2O = H^3PO^3 + 3HCl.$$
$$PCl^5 + 4H^2O = H^3PO^4 + 5HCl.$$

The two chlorides of antimony are decomposed more slowly. Trichloride of bismuth requires prolonged treatment with water to effect its thorough decomposition, which, however, takes place readily at a boiling temperature. Stannic chloride, even at a boiling temperature, is decomposed very imperfectly. The sesquichloride of aluminium and protochloride of magnesium, &c., are decomposed by steam, with evolution of hydrochloric acid, at temperatures considerably below redness:

$$2Al^2Cl^3 + 3H^2O = Al^4O^3 + 6HCl.$$
$$2MgCl + H^2O = Mg^2O + 2HCl.$$

Moreover, hydrochloric acid results from the reaction of chloride of phosphorus, chloride of antimony, and some other chlorides, usually hyperchlorides, not only with water, but with most oxyhydrogenised compounds (pp. 897—900).

4. Hydrochloric acid is a constant attendant upon the direct action of chlorine on hydrogenised substances. A solution of chlorine in water is converted, when exposed to light, into hydrochloric and hypochlorous acids: $Cl^2 + H^2O = HCl + HClO$. Chlorine instantly decomposes sulphydric acid, with formation of hydrochloric acid and separation of sulphur: $Cl^2 + H^2S = 2HCl + S$. Phosphoretted and arsenetted hydrogen are likewise decomposed by chlorine, with formation of hydrochloric acid. Numerous organic compounds also are decomposed by chlorine, one portion of that element uniting with the whole or with part of the hydrogen, and an equal portion taking the place of the hydrogen thus removed: *e. g.*

$$\underset{\text{Acetic acid.}}{C^2H^4O^2} + 3Cl^2 = \underset{\text{Trichlor-acetic acid.}}{C^2HCl^3O^2} + 3HCl.$$

Hydrochloric acid also results from the inverse action of hydrogen upon a chlorine compound, as when ignited chloride of nickel is subjected to a current of hydrogen, thus: $NiCl + H = HCl + Ni$.

Properties.—Hydrochloric acid is a colourless gas, having a strong acid taste, and a pungent irritating odour. Its specific gravity (air = 1) is, according to the determination of Biot and Gay-Lussac, 1·27; by calculation, it is $\frac{35\cdot5 + 1}{2} \times 0\cdot0693 = 1\cdot265$. It forms opaque white fumes in the air, owing to its union with, and condensation of, the atmospheric moisture. In perfectly dry air these fumes are not produced. The gas is extremely soluble in water. When a flask of dry hydrochloric acid is opened under water, the whole of the gas is absorbed in an instant, and the flask not unfrequently broken by the violent rush of liquid. At mean temperature (15° C.) water dissolves about 458 times its volume of the gas (see GASES, ABSORPTION OF). At the temperature of 10°, under a pressure of 40 atmospheres, hydrochloric acid is condensed into a colourless liquid, having a specific gravity 1·27. It has never been solidified. Hydrochloric acid is not inflammable, and extinguishes most burning bodies, but when a piece of potassium is introduced by means of an iron wire into a tube full of the gas retained over mercury, and is then heated to redness by a spirit-lamp applied externally, it undergoes combustion, unites with the chlorine, and leaves the hydrogen, which is eventually found to occupy exactly one half the volume of the original gas: $HCl + K = KCl + H$.

Solution of hydrochloric acid is usually made from common salt and sulphuric acid diluted with about two-thirds its bulk of water. The reaction is effected in a retort to which a gentle heat is applied, and the evolved gas is condensed in a vessel or series of vessels of distilled water. The condensing liquid increases considerably in bulk, and may eventually be made to acquire a specific gravity of 1·21, under which circumstances it consists of one atom of hydrochloric acid, HCl, dissolved in three atoms of water, H^2O. Solution of hydrochloric acid has usually a specific gravity of 1·162, and then consists of one atom of hydrochloric acid HCl, dissolved in four atoms of water, H^2O.

Commercial muriatic acid is made by heating in iron cylinders two proportions of common salt, with as much brown sulphuric acid as contains one proportion of real acid, and condensing the evolved gas in water contained in a series of stoneware Woulfe's bottles. The reaction is: $H^2SO^4 + 2NaCl = Na^2SO^4 + 2HCl$. For details, see *Ure's Dictionary of Arts, Manufactures and Mines*, ii. 481.—Pelouze et Frémy, *Traité de Chimie générale*, 3^{me} éd. i. 436.—Payen, *Précis de Chimie industrielle*, 4^{me} éd. i. 264.)

The commercial acid, which frequently contains, as impurities, sulphurous acid, arsenious acid, sesquichloride of iron, stannic chloride, and even free chlorine, may be partly purified by dilution and redistillation. A pure solution of hydrochloric acid is usually colourless, but when in large quantities, has a very pale yellowish green tint. The slight yellow colour of miscalled pure acid is generally due to the presence of free chlorine, but the bright deep yellow of the commercial acid results from the presence of chloride of iron. The introduction of a small quantity of organic matter, as by contact with a cork, will likewise impart a yellow colour to hydrochloric acid otherwise pure.

A strong solution of hydrochloric acid evolves fumes on exposure to air. When boiled, it gives off hydrochloric acid gas, until the temperature slightly exceeds 100° C., when there distils over a diluted solution of the acid, having a specific gravity of 1·1, and consisting of 1 atom of hydrochloric acid, HCl, dissolved in 8 atoms of water, H^2O.

From the experiments of **Roscoe**, however (Chem. Soc. Qu. J. xiii. 156), it appears that the composition of aqueous hydrochloric acid (and of other aqueous acids), of constant boiling point, varies with the pressure, and that there exists for each pressure a corresponding aqueous acid, which undergoes no change in composition when distilled under this pressure, and therefore has a constant boiling point. In table A, column P shows the pressure in metres of mercury under which aqueous hydrochloric acid must be distilled to attain the composition given in the next column.

TABLE A.—*Percentage of* HCl *in aqueous Hydrochloric Acid boiling under different Pressures.*

P	Percentage of HCl.	P	Percentage of HCl.	P	Percentage of HCl.	P	Percentage of HCl.
0·05	23·2	0·7	20·4	1·3	19·3	2·0	18·5
0·1	22·9	0·76	20·14	1·4	19·1	2·1	18·4
0·2	22·3	0·8	20·2	1·5	19·0	2·3	18·3
0·3	21·8	0·9	19·9	1·6	18·9	2·4	18·1
0·4	21·4	1·0	19·7	1·7	18·8	2·5	18·0
0·5	21·1	1·1	19·5	1·8	18·7		
0·6	20·7	1·2	19·4	1·9	18·6		

The acid which boils constantly under the pressure 0·76 met., and contains 20·24 per cent. HCl, is the hydrate above mentioned, $HCl.8H^{2}O$. The table shows that the percentage of HCl in the aqueous acid of constant boiling point, diminishes with increase of pressure.

When aqueous hydrochloric acid is vaporised by passing a current of dry air through it at a *given temperature*, a point is likewise reached beyond which no decomposition occurs. In Table B the first column gives the temperatures, the second the percentage of HCl contained in the acid, unalterable at the corresponding temperature.

TABLE B.—*Percentage of* HCl *in Aqueous Hydrochloric Acid of constant composition at different Temperatures.*

T°	Percentage of HCl.	T°	Percentage of HCl.	T°	Percentage of HCl.	T°	Percentage of HCl.
0° C.	25·0	30° C.	24·1	60° C.	23·0	90° C.	21·4
5	24·9	35	23·9	65	22·8	95	21·1
10	24·7	40	23·8	70	22·6	100	20·7
15	24·6	45	23·6	75	22·3		
20	24·4	50	23·4	80	22·0		
25	24·3	55	23·2	85	21·7		

The specific gravity of aqueous hydrochloric acid, of various degrees of concentration has been determined by Ure and by E. Davy. The results are given in Tables C and D; it will be observed that the specific gravities as determined by Davy are rather lower for each percentage of HCl than those of Ure.

TABLE C.—*Percentage of* HCl *in Aqueous Hydrochloric Acid at* 25° C. (77° F.) *according to* E. Davy.

Sp. Gr.	HCl.	Sp. Gr.	HCl.	Sp. Gr.	HCl.	Sp. Gr.	HCl.

Aqueous hydrochloric acid possesses powerful acid properties, reddens litmus, tastes intensely sour, effervesces with carbonates, and dissolves many metals with evolution of hydrogen. It does not bleach vegetable colours or dissolve gold leaf. W. O.

CHLORHYDRIC ETHERS. See Chlorides of Alcohol-Radicles (p. 897).

CHLORHYDRINS. (Berthelot, Ann. Ch. Phys. [3] xli. 296.—Berthelot and De Luca, *ibid.* xlviii. 304; lii. 433.)—These compounds, which are precisely analogous to the bromhydrins (p. 667), are the chlorhydric ethers of glycerin, and may be regarded as derived therefrom by the substitution of one or more atoms of chlorine for an equivalent quantity of peroxide of hydrogen. They are produced, either by the action of hydrochloric acid or of the chlorides of phosphorus on glycerin; the latter method does not however yield very good products.

Monochlorhydrin, $C^3H^7ClO^2 = (C^3H^5)'''.(HO)^2.Cl$, is obtained by saturating gently heated glycerin with hydrochloric acid gas; then keeping the liquid at 100° C. for some hours; saturating with carbonate of sodium; agitating with ether; distilling the residue left after evaporation of the ether; and again treating it with carbonate of sodium and ether. It is a neutral oil, having a fresh ethereal odour and a sweet taste, with pungent after-taste. Specific gravity 1·31. It remains perfectly fluid at −35° C.; boils at 227°; burns with a white, green-edged flame, emitting hydrochloric acid. Oxide of lead saponifies it slowly. It does not immediately precipitate nitrate of silver. It mixes with its own bulk of water. With 8 or 10 times its bulk of water, it forms a very stable emulsion. It also mixes with ether.

Dichlorhydrin, $C^3H^6Cl^2O = (C^3H^5)'''.HO.Cl^2$, is obtained by heating a solution of glycerin in 10 or 12 times its weight of fuming hydrochloric acid, to 100° C. for three or four days, purifying the product with carbonate of sodium and ether as above, and evaporating, first over the water-bath, then in vacuo. It is a neutral oil, having an ethereal odour. Specific gravity 1·37. It boils at 178° C.; remains quite fluid at −35°; burns like the preceding; is easily decomposed by potash, yielding chloride of potassium and glycerin; mixes with ether, but does not form a stable emulsion with water.

Trichlorhydrin; Trichloride of Glyceryl, $C^3H^5Cl^3$.—Produced by the action of pentachloride of phosphorus on dichlorhydrin:

$$C^3H^4Cl^2O + PCl^5 = PCl^3O + HCl + C^3H^5Cl^3.$$

It is a neutral liquid, much more stable than tribromhydrin. Volatilises at about 155° C. (Berthelot and De Luca.)

Epichlorhydrin. Oxychloride of Glyceryl. C^3H^5ClO.—Obtained by treating dichlorhydrin with hydrochloric acid gas, or with the fuming acid. Neutral oil, resembling dichlorhydrin. Distils between 120° and 130° C. (Berthelot.)

Epidichlorhydrin. Dichloride of Glycerylene. $C^3H^4Cl^2$. — Produced in small quantity in the preparation of trichlorhydrin and bromodichlorhydrin, probably by a secondary reaction, inasmuch as it differs from dichlorhydrin by H^2O, and from trichlorhydrin by HCl. It is isolated and purified by repeated fractional distillation. Neutral liquid, volatile at about 120° C. Treated with moist oxide of silver, it slowly reproduces glycerin. (Berthelot and De Luca.)

Dibromochlorhydrin, $C^3H^5Br^2Cl$.—Produced by the action of pentachloride of phosphorus on dibromhydrin. Neutral liquid, volatile at about 200° C. With moist oxide of silver at 100°, it slowly reproduces glycerin. It is isomeric with dibromide of chlorotritylene, $C^3H^5ClBr^2$.

Bromodichlorhydrin, $C^3H^5BrCl^2$.—Produced by the action of pentabromide of phosphorus on dichlorhydrin. Neutral liquid, volatile at about 176° C. Isomeric with dichloride of bromotritylene.

With moist oxide of silver at 100°, it slowly reproduces glycerin; at the same time, however, a small quantity of carbonic anhydride is formed by oxidation, together with crystalline scales, which appear to be propionate of silver:

$$C^3H^5BrCl^2 + 3H^2O = \underset{\text{Glycerin.}}{C^3H^8O^3} + 2HCl + HBr$$

and

$$C^3H^5BrCl^2 + 2H^2O = \underset{\text{Propionic acid.}}{C^3H^6O^2} + 2HCl + HBr$$

For the Acetochlorhydrins, see p. 25; Benzochlorhydrins (p. 547.)

CHLORHYDROPHENIDE. Chloride of Phenyl. (See Phenyl.)

CHLORHYDROPROTEIC ACID. A name applied by Mulder (J. pr. Chem. xvii. 316), to the precipitate formed by hydrochloric acid in a solution of albumin, said by Mulder to contain 3·7 per cent. of hydrochloric acid. It is probably however nothing but albumin.

CHLORIDES. The term chloride is applied to all compounds of chlorine which may be derived from one or more atoms of hydrochloric acid, H^nCl^n, by the substitution of a metal or other radicle (which may itself contain chlorine), for an equivalent quantity of hydrogen. Those which are volatile contain, in two volumes of vapour, 1, 2, 3, &c. atoms of chlorine, according as the radicle with which the chlorine is associated is mono-, di-, tri-atomic, &c.*, thus:

2 vol.	chloride of	ethyl,	$C^2H^5.Cl$,	contain	1	at. chlorine
„	„	sulphuryl,	$(SO^2)''.Cl^2$	„	2	„
„	„	boron,	$\overset{'''}{B}.Cl^3$	„	3	„
„	„	silicium,	$\overset{''''}{Si}Cl^4$	„	4	„

Chlorides may be conveniently divided into the following groups, each of which contains compounds derived from one or more atoms of hydrochloric acid.

a. **Metallic Chlorides.** Chlorine combines with all metals, the number of chlorine-atoms in the resulting molecule varying from 1 to 7.

a. Chlorides, with one atom of chlorine, formed on the type of the single atom of hydrochloric acid, HCl, namely, protochlorides, MCl, and hemichlorides, or subchlorides, M^2Cl. The greater number of metals form protochlorides, all indeed, except aluminium, antimony, arsenic, bismuth, tantalum, titanium, tungsten, vanadium and zirconium. The protochlorides are all more or less soluble in water, except those of silver and platinum, which are quite insoluble. The protochlorides of gold, platinum,

---

* If, however, the radicle contains chlorine, this statement must be understood as applying only to the portion of chlorine which is not thus included, and is removable by water or by aqueous potash; for example, 2 vols. chloride of trichloracetyl, $C^2Cl^3O.Cl$ contain 4 atoms of chlorine; but only one of these is removable by water, the compound, treated with water, yielding hydrochloric acid and trichloracetic acid ($C^2Cl^3O.Cl + H^2O = HCl + C^2Cl^3O.H.O$).

and palladium, are completely decomposed at a red heat; that of copper, partially. The other protochlorides melt when heated, and volatilise unchanged at higher temperatures. Several hydrated protochlorides, those of magnesium and zinc, for instance, are resolved more or less completely by heat into metallic oxide and hydrochloric acid. The fused protochlorides are electrolytic.

The *hemi-atomic metals*, especially copper and mercury, form subchlorides, containing, *e. g.* Cu^2Cl, Hg^2Cl. They are insoluble in water, and under certain circumstances manifest a tendency to break up into metal and protochloride.

β. *Chlorides with two atoms of chlorine, formed on the type* H^2Cl^2, *namely*, Dichlorides, $M''Cl^2$. The metals which form dichlorides, are molybdenum, palladium, platinum, tellurium, tin, titanium, tungsten, and vanadium. The dichlorides of platinum and palladium give off at a gentle heat one half, and at a stronger heat the whole of their chlorine. The others are easily volatile.

γ. *Chlorides with three atoms of chlorine, formed on the type* H^3Cl^3, namely, Trichlorides, $M'''Cl^3$, and sesquichlorides, $(M^2)'''Cl^3$.—The metals which form trichlorides are antimony, arsenic, bismuth, gold, molybdenum, tungsten, and vanadium. Trichloride of gold is reduced at a gentle heat to protochloride, which at a higher temperature is resolved into chlorine and metal. The rest volatilise unchanged. The trichlorides of antimony and bismuth are very fusible solids; the rest are liquids. The volatile trichlorides are decomposed by water, yielding hydrochloric acid and an oxychloride, thus: $BiCl^3 + H^2O = 2HCl + BiClO$.

The sesquichlorides are formed from a triple molecule of hydrochloric acid, by the substitution of 2 at. of a sesqui-atomic metal for 3 at. hydrogen; the metals which form them are aluminium, cerium (?), chromium, iron, and manganese. The cerium and manganese compounds are known only as hydrates; the rest are fusible and volatile solids. They are all soluble in water, and are partially decomposed by heat.

δ. *Chlorides with four atoms of chlorine, formed on the type* H^4Cl^4, *namely*, Tetrachlorides. These are formed only by the metals tin, titanium, and zirconium. The first two are liquids, the third solid: they are all volatile, and their general behaviour shows that two of the chlorine-atoms are retained less forcibly than the other two. The tetrachlorides of tin and titanium are soluble in water; the zirconium-compound is decomposed by water.

ε. *Chloride with 5 at. chlorine.*—Pentachloride of antimony, $SbCl^5$. Volatile liquid, decomposed by water.

There are no *hexachlorides* known, and only one *heptachloride*, namely, the heptachloride of manganese, Mn^2Cl^7.

Formation of Metallic Chlorides.—Chlorides are generally prepared by one or other of the following processes. α. By acting upon the metal with chlorine gas. This method is frequently employed for the preparation of anhydrous chlorides. The pentachloride of antimony and protochloride of copper are examples of chlorides sometimes produced in this manner. The chlorides of gold and platinum are usually prepared by acting upon the metals with nascent chlorine, developed by the mutual action of hydrochloric and nitric acids. Sometimes, on the other hand, the metal is in a nascent state, as when titanic chloride is formed by passing a current of chlorine over a heated mixture of charcoal and titanic anhydride. The chlorides of aluminium and chromium may be obtained by similar processes.

β. Chlorine gas, by its action upon metallic oxides, drives out the oxygen, and unites with the respective metals to form chlorides. This reaction sometimes takes place at ordinary temperatures, as is the case with oxide of silver; sometimes only at a red heat, as is the case with the oxides of the alkali- and alkaline earth-metals. The hydrates and carbonates of these last metals, when dissolved or suspended in hot water and treated with excess of chlorine, are converted, chiefly into chlorides, partly into chlorates.

γ. Many metallic chlorides are prepared by acting upon the metals with hydrochloric acid. Zinc, cadmium, iron, nickel, cobalt, and tin dissolve readily in hydrochloric acid, with liberation of hydrogen; copper only in the strong boiling acid; silver, mercury, palladium, platinum, and gold, not at all. Sometimes the metal is substituted, not for hydrogen, but for some other metal. Stannous chloride, for instance, is frequently made by distilling metallic tin with mercuric chloride, thus: $2HgCl + Sn = SnCl^2 + Hg^2$.

δ. Or the oxide, hydrate, or carbonate of metal may be dissolved in hydrochloric acid. In this way the hydrated protochloride of copper and sesquichloride of iron are usually made:

$$Cu^2O + 2HCl = H^2O + 2CuCl.$$
$$Fe^2H^3O^3 + 3HCl = 3H^2O + Fe^2Cl^3.$$

With a peroxide, the reaction is accompanied by an evolution of chlorine, thus:

$$Pb^2O^2 + 4HCl = 2H^2O + 2PbCl + Cl^2.$$

ε. Chloride of silver and mercurous chloride, which are insoluble in water, and chloride of lead, which is but sparingly soluble, are easily formed by precipitating any of the corresponding soluble salts with a soluble chloride, thus:

$$NaCl + AgNO^3 = AgCl + NaNO^3.$$

Decompositions.—1. The action of heat upon chlorides has been already noticed. Most protochlorides volatilise at high temperatures, without decomposition; the higher chlorides give off part of their chlorine when heated.—2. Some chlorides which resist the action of heat alone are decomposed by ignition in the air, yielding metallic oxides and free chlorine: this is the case with the chlorides of iron and manganese; but most protochlorides remain undecomposed, even in this case.—3. All metallic chlorides, excepting those of the alkali-metals and earth-metals, are decomposed at a red heat by *hydrogen* gas, with formation of hydrochloric acid: in this way, metallic iron may be obtained in fine cubical crystals. Chloride of silver placed in contact with metallic zinc or iron, under dilute sulphuric or hydrochloric acid, is reduced to the metallic state by the *nascent hydrogen.*—4. Metallic chlorides, which are not decomposed by heat alone, likewise resist the action of *charcoal* at a white heat, but if *aqueous vapour* is likewise present, decomposition takes place, the metal being reduced, and hydrochloric acid formed, together with an oxide of carbon, *e.g.*:

$$2AgCl + H^2O + C = Ag^2 + 2HCl + CO.$$

—5. Metallic chlorides are not decomposed by heating with *sulphur*, but *phosphorus* decomposes several of them.—6. Those metallic chlorides which are not decomposed by heat alone, likewise resist decomposition when heated to whiteness with *boric anhydride*, or *silicic anhydride*; but if water is present, hydrochloric acid is evolved, and a borate or silicate of the metal is produced. Vapour of *sulphuric anhydride*, however, decomposes certain metallic chlorides, a sulphate being formed, and a mixture of equal volumes of chlorine and sulphurous anhydride evolved, *e.g.*:

$$2NaCl + 2SO^3 = Na^2SO^4 + SO^2 + Cl^2.$$

—7. *Sulphuric, phosphoric, boric*, and *arsenic acids*, decompose most metallic chlorides, sometimes at ordinary, sometimes at higher temperatures.—8. All metallic chlorides heated with *peroxide of lead* or *manganese* and *sulphuric acid*, give off chlorine, *e.g.*:

$$2NaCl + Mn^2O^2 + 2H^2SO^4 = Na^2SO^4 + Mn^2SO^4 + 2H^2O + Cl^2.$$

—9. Distilled with *sulphuric acid* and *chromate of potassium*, they yield a dark bluish-red distillate of chloro-chromic acid.—10. Some metallic chlorides are decomposed by *water*, forming hydrochloric acid and an oxychloride, *e.g.*: $BiCl^3 + H^2O = 2HCl + BiClO$. The chlorides of antimony and stannous chloride are decomposed in a similar manner.—11. All soluble chlorides give with solution of *nitrate of silver*, a white precipitate of chloride of silver, easily soluble in ammonia, insoluble in nitric acid. With *mercurous nitrate*, they yield a white curdy precipitate of mercurous chloride, blackened by ammonia; and with *lead-salts*, not too dilute, a white crystalline precipitate of chloride of lead, soluble in excess of water.

Combinations.—Metallic chlorides unite with each other and with the chlorides of the non-metallic elements, forming such compounds as chloromercurate of potassium, $KCl.HgCl$, chloroplatinate of sodium, $NaCl.PtCl^2$, chloriodate of potassium, $KCl.ICl^3$, &c. They also combine with oxides and sulphides, forming oxychlorides and sulphochlorides. Metallic chlorides likewise combine in definite proportions with ammonia and organic bases; the chlorides of platinum form with ammonia the compounds $NH^3.PtCl$, $2NH^3.PtCl$, $NH^3.PtCl^2$, and $2NH^3.PtCl^2$; mercuric chloride forms with phenylamine the compound $C^6H^7N.HgCl$; with chinoline, $C^9H^7N.2HgCl$, &c. Many of these compounds may be regarded as chlorides of metalloïdal radicles, formed on the ammonium type: thus, ammonio-protochloride of platinum, $NH^3.PtCl$ = chloride of platammonium $(NH^3Pt).Cl$.

Many metallic chlorides are soluble in alcohol, ether, volatile oils, &c.

b. **Chlorides of Organo-metallic Radicles** (including Phosphorus-bases).—These compounds, which bear considerable resemblance to the simple metallic chlorides, are produced, either by the direct union of chlorine with the organo-metallic radicle, or by the action of hydrochloric acid on the oxide or hydrate of that radicle. Some of them are volatile liquids; others crystalline solids. They contain 1, 2, 3, or 4 at. of chlorine associated with 1 molecule of the organo-metallic radicle, those which contain an even number of atoms of alcohol-radicle forming mono- and trichlorides, while those which contain an uneven number of atoms of alcohol-radicle form di- and tetrachlorides, thus:

Arsen-monomethyl	forms	$AsMeCl^3$	and	$AsMeCl^4$
Arsen-dimethyl	,,	$AsMe^2Cl$	,,	$AsMe^2Cl^3$
Stib-triethyl	,,	$SbMe^3Cl^2$		
Stib-tetramethylium	,,	$SbMe^4Cl$		

All these compounds may be regarded as derived from a molecule of tri- or pentachloride of arsenic or antimony by the substitution of an alcohol-radicle for an equivalent quantity of chlorine (pp. 339, 397, 411).

3. **Chlorides of Alcohol-Radicles.** *Hydrochloric or Chlorhydric Ethers.*—These compounds may be regarded as derived from hydrochloric acid in a similar manner to the metallic chlorides, or from the corresponding alcohols by the substitution of chlorine for an equivalent quantity of peroxide of hydrogen, *e. g.*:

Chloride of ethyl,	$C^2H^5.Cl$	from	Ethylic alcohol,	$C^2H^5.HO$
Chloride of ethylene,	$C^2H^4.Cl^2$	,,	Glycol,	$C^2H^4.(HO)^2$
Chloride of glyceryl,	$C^3H^5.Cl^3$	,,	Glycerin,	$C^3H^5.(HO)^3$

a. The *monatomic alcoholic chlorides* are obtained:

1. By the action of hydrochloric acid on the alcohols:

$$C^2H^5.H.O + HCl = H^2O + C^2H^5.Cl.$$

2. By the action of the chlorides of phosphorus, or of oxychloride of phosphorus, on the alcohols:

$$3(C^2H^5.H.O) + PCl^3 = H^3PO^3 + 3C^2H^5Cl.$$
$$3(C^2H^5.H.O) + PCl^3O = H^3PO^4 + 3C^2H^5Cl.$$

3. By the action of chlorine on the corresponding hydrides. This reaction has been observed only in the case of hydride of benzyl (p. 573).

Most of these monatomic chlorides are liquids more volatile than the corresponding alcohols: one, viz. chloride of methyl, is gaseous at ordinary temperatures, and chloride of cetyl is solid. Treated with alcoholic potash, they yield chloride of potassium and an alcohol:

$$C^2H^5Cl + KHO = KCl + C^2H^5.H.O$$

When recently prepared, they do not precipitate nitrate of silver immediately; but when they are heated with it in sealed tubes, a slow precipitation takes place. Sodium at ordinary temperatures decomposes them, with formation of chloride of sodium and an alcohol-radicle:

$$\underset{\text{Chloride of octyl.}}{2C^8H^{17}Cl} + Na^2 = 2NaCl + \underset{\text{Octyl.}}{C^8H^{17}.C^8H^{17}}.$$

But if heat be applied, the sodium assumes a violet tint and swells up considerably. The liquid then becomes hot; hydrogen is evolved; the violet colour disappears; and a pasty mass is ultimately obtained, consisting of chloride of sodium and an oil, which is the corresponding hydrocarbon, C^nH^{2n}: thus, with chloride of octyl:

$$2(C^8H^{17}.Cl) + Na^2 = 2(C^8H^{16}Na.Cl) + HH$$

and:

$$\underset{\text{Violet substance.}}{C^8H^{17}Na.Cl} = NaCl + \underset{\text{Octylene.}}{C^8H^{16}}.$$

The same violet substance is produced by the simultaneous action of chlorine and sodium on octylene. It quickly turns white in contact with the air, yielding soda and chloride of sodium, and is quickly decomposed by water, alcohol, and other liquids containing oxygen (Bouis, N. Ann. Chim. Phys. xliv. 114). A similar violet substance is formed by the action of potassium on chloride of phenyl.

β. The *diatomic alcoholic chlorides* are produced: 1. By the direct union of chlorine with the corresponding diatomic hydrocarbons, *e. g.* chloride of ethylene, chloride of tetrylene, &c.—2. By the action of pentachloride of phosphorus on the corresponding alcohols, *e. g.*:

$$\underset{\text{Glycol.}}{C^2H^4.H^2.O^2} + 2PCl^5 = \underset{\text{Chloride of ethylene.}}{C^2H^4Cl^2} + 2POCl^3 + 2HCl.$$

Two series of these chlorides are known, containing the radicles C^nH^{2n}, homologous with ethylene, and C^nH^{2n-8}, homologous with benzylene.

The chlorides $C^nH^{2n}Cl^2$, are liquids, for the most part volatile without decomposition. They are decomposed by chlorine, yielding substitution-products. Heated with alcoholic potash, they yield chloride of potassium, and the chloride of an aldehyde-radicle:

$$C^2H^4Cl^2 + KHO = C^2H^3Cl + KCl + H^2O.$$

Sulphide of potassium simply converts them into sulphides of diatomic alcohol-radicles:

$$C^2H^4Cl^2 + K^2S = 2KCl + C^2H^4S.$$

Heated with ammonia in sealed tubes, they appear to yield the same products as the corresponding bromides, viz. diamines containing 1, 2, or 3 at. of the radicles C^nH^{2n}; but the reactions have not been so much examined as those of the bromides. (See AMMONIUM-BASES, p. 196; also ETHYLENE-BASES.)

The chlorides $C^nH^{2n-8}Cl^2$, are also volatile liquids heavier than water. Heated with alcoholic potash, they yield chloride of potassium and an aldehyde: *e. g.* chloride of benzylene yields bitter-almond oil. (Wicke, Ann. Ch. Pharm. cii. 356):

$$C^7H^6Cl^2 + KHO = KCl + HCl + C^7H^6O.$$

Ammonia heated with chloride of benzylene in sealed tubes, acts in like manner (Wicke). With alcoholic sulphide of potassium, they are decomposed like the chlorides last mentioned, yielding diatomic sulphides.

γ. Of *triatomic alcoholic chlorides*, only one is known, viz. chloride of glyceryl or trichlorhydrin, $(C^3H^5)'''Cl^3$, which is produced by the action of pentachloride of phosphorus on dichlorhydrin, $(C^3H^5)'''\begin{matrix}HO\\Cl^2\end{matrix}$. (See CHLORHYDRINS, p. 894.)

4. **Chlorides of Aldehyde-Radicles.**—These are monatomic chlorides of the general form $C^nH^{2n-1}Cl$, isomeric with the monochlorinated diatomic alcohol-radicles, *e. g. chloride of vinyl*, $C^2H^3.Cl$, with chlorethylene, $C^2(H^3Cl)$. They are obtained by the action of alcoholic potash on the chlorides of the diatomic alcohol-radicles (p. 987), sometimes also by that of oxychloride of carbon on the aldehydes, *e. g.* C^2H^3Cl from acetic aldehyde, C^2H^4O (Harnitzky, p. 107). It is probable also that they might be obtained by treating the aldehydes with pentachloride of phosphorus; as butyral, the isomer of butylic aldehyde, yields when thus treated, the compound C^4H^7Cl (p. 689).

These chlorides are volatile liquids, except chloride of vinyl, which is gaseous at ordinary temperatures. Chlorine converts them into dichlorides of chlorinated alcohol-radicles.

5. **Chlorides of Acid Radicles.**—These compounds may be derived from acids by the substitution of chlorine for peroxide of hydrogen, *e. g.*:

Chloride of acetyl,	$C^2H^3O.Cl$	from	Acetic acid,	$C^2H^3O.HO$
Chloride of sulphuryl,	$(SO^2)''.Cl^2$	,,	Sulphuric acid,	$(SO^2)''(HO)^2$
Chloride of phosphoryl,	$(PO)'''.Cl^3$	,,	Phosphoric acid,	$(PO)'''.(HO)^3$

α. Monatomic acid chlorides are mostly derived from organic acids; in fact, the only inorganic compounds of this class are *hydrochloric acid*, HCl; *chloride of azotyl*, NO.Cl, produced by the direct combination of chlorine and nitric oxide gases, or by the decomposition of nitromuriatic acid; and *chloride of nitryl*, $NO^2.Cl$, produced by the action of oxychloride of phosphorus on nitrate of lead: $3PbNO^3 + PCl^3O = Pb^3PO^4 + 3NO^2Cl$, or by the action of chlorhydrosulphuric acid upon nitre: $KNO^3 + HClSO^4 = NO^2Cl + KHSO^4$. Free chlorine, ClCl, may be regarded as the chloride corresponding to hypochlorous acid, Cl.HO.

The chlorides of monatomic organic acids are obtained: by the action of the chlorides of phosphorus, or of the oxychloride, on the corresponding acids:

$$\underset{\text{Benzoic acid.}}{C^7H^5O.H.O} + PCl^3.Cl^2 = \underset{\substack{\text{Chloride of}\\ \text{benzoyl.}}}{C^7H^5O.Cl} + HCl + PCl^3.O.$$

or of trichloride or oxychloride of phosphorus on salts of the same acids:

$$3(\underset{\substack{\text{Benzoate of}\\ \text{potassium.}}}{C^7H^5O.K.O}) + PCl^3O = K^3PO^4 + 3(\underset{\substack{\text{Chloride of}\\ \text{benzoyl.}}}{C^7H^5O.Cl}).$$

sometimes also by the action of chlorine on the corresponding hydrides (aldehydes):

$$C^7H^5O.H + Cl^2 = C^7H^5O.Cl + HCl.$$

They are mostly fuming volatile liquids (chloride of cyanogen, CN.Cl, is gaseous), remarkable for the facility with which they are decomposed by water and its derivatives (alcohols, alkalis, alkaline salts, &c.), and by ammonia and the compound ammonias.

Water transforms them into hydrochloric acid and a monobasic organic acid:

$$\underset{\substack{\text{Chloride of}\\ \text{acetyl.}}}{C^2H^3O.Cl} + H^2O = HCl + \underset{\text{Acetic acid.}}{C^2H^3O.H.O}.$$

With alkalis, in like manner, they yield the alkaline salts of the corresponding acids, and with alcohols, compound ethers:

$$\underset{\substack{\text{Chloride of}\\ \text{acetyl.}}}{C^2H^3O.Cl} + \underset{\text{Alcohol.}}{C^2H^5.H.O} = HCl + \underset{\text{Acetate of ethyl.}}{C^2H^3O.C^2H^5.O}.$$

Distilled with the alkaline salts of monobasic acids, they yield anhydrides:

$$\underset{\substack{\text{Chloride of}\\ \text{acetyl.}}}{C^2H^3O.Cl} + \underset{\substack{\text{Acetate of}\\ \text{potassium.}}}{C^2H^3O.K.O} = KCl + \underset{\substack{\text{Acetic}\\ \text{anhydride.}}}{(C^2H^3O)^2O}.$$

$$\underset{\substack{\text{Chloride of}\\ \text{acetyl.}}}{C^2H^3O.Cl} + \underset{\substack{\text{Benzoate of}\\ \text{potassium.}}}{C^7H^5O.K.O} = KCl + \underset{\substack{\text{Aceto-benzoic}\\ \text{anhydride.}}}{C^2H^3O.C^7H^5O.O}.$$

With ammonia, or carbonate of ammonium, they yield primary amides:

$$\underset{\substack{\text{Chloride of}\\\text{benzoyl.}}}{C^7H^5O.Cl} + NH^3 = HCl + \underset{\text{Benzamide.}}{N.H^2.C^7H^5O}.$$

and with compound ammonias they yield alkalamides:

$$\underset{\substack{\text{Chloride of}\\\text{benzoyl.}}}{C^7H^5O.Cl} + \underset{\substack{\text{Pheny-}\\\text{lamine.}}}{N.H^2.C^6H^5} = HCl + \underset{\text{Phenyl-benzamide.}}{N.H.C^6H^5.C^7H^5O}.$$

In like manner, with primary amides they form secondary amides:

$$\underset{\substack{\text{Chloride of}\\\text{benzoyl.}}}{C^7H^5O.Cl} + \underset{\text{Acetamide.}}{N.H^2.C^2H^3O} = HCl + \underset{\text{Aceto-benzamide.}}{N.H.C^2H^3O.C^7H^5O}.$$

β. *Diatomic acid chlorides*, derived from a double molecule of hydrochloric acid, and corresponding to dibasic acids. Such are:

Chloride of carbonyl (phosgene)	$(CO)''.Cl^2$
Chloride of sulphuryl	$(SO^2)''.Cl^2$
Chloride of succinyl	$(C^4H^4O^2)''.Cl^2$

Two volumes of the vapour of these chlorides contain 2 atoms of chlorine capable of conversion into a metallic chloride by the action of a mineral alkali.

They are obtained by the action of pentachloride of phosphorus on dibasic acids or anhydrides, the reaction, as shown by Williamson, consisting of two stages, the first resulting in the formation of a chlorinated acid, the second in that of a chloride, *e.g.* with sulphuric acid:

$$\left.\begin{matrix}(SO^2)''\\H^2\end{matrix}\right\}O^2 + PCl^2.Cl^3 = \underset{\substack{\text{Chlor-hydro-}\\\text{sulphuric acid.}}}{(SO^2)''\left\{\begin{matrix}HO\\Cl\end{matrix}\right.} + HCl + POCl^3.$$

$$(SO^2)''\left\{\begin{matrix}HO\\Cl\end{matrix}\right. + PCl^2.Cl^3 = \underset{\substack{\text{Chloride of}\\\text{sulphuryl.}}}{(SO^2)''.Cl^2} + HCl + POCl^3.$$

Chloride of sulphuryl and chloride of carbonyl are also formed by the direct combination of chlorine with the radicles, under the influence of light.

The diatomic acid chlorides are liquid at ordinary temperatures, with the exception of phosgene, which is gaseous. Their reactions are similar to those of the monatomic chlorides.

γ. *Triatomic Acid Chlorides*, corresponding to tribasic acids, and containing in two volumes of vapour, 3 vol. chlorine capable of conversion into a metallic chloride by the action of an alkali. Such are:

Trichloride of phosphorus	PCl^3
Chloride of phosphoryl (oxychloride of phosphorus) . .	$PO.Cl^3$
Chloride of sulphophosphoryl	$PS.Cl^3$
Chloride of boron	$B.Cl^3$
Chloride of cyanogen (solid)	$(CN)^3.Cl^3$

The trichlorides of arsenic and antimony must also be regarded as acid chlorides. The explosive compound, commonly called chloride of nitrogen, is perhaps also a trichloride, NCl^3; but, according to some authorities, it contains hydrogen.

Acid trichlorides are produced, for the most part, by the direct action of chlorine on the radicles. Chloride of phosphoryl is produced by the action of water, and of various derivatives of water, on the pentachloride, $PCl^5 + H^2O = 2HCl + POCl^3$; and chloride of sulphophosphoryl, in like manner by the action of sulphydric acid on the pentachloride. All these compounds are decomposed by water and its derivatives in the same manner as the mono- and di-atomic chlorides, yielding acids, salts, and compound ethers. Most of them unite with monatomic metallic chlorides, forming double chlorides.

δ. *Tetratomic Acid Chlorides*, containing 4 at. chlorine in 2 vols. of vapour. Some of the tetratomic metallic chlorides are of acid character, viz. $SnCl^4$ and $TiCl^4$; chloride of silicium, $SiCl^4$, is also tetratomic. The only organic compound of this class is tetrachloride of carbon, CCl^4 (p. 765). In these chlorides, two of the chlorine-atoms are retained less forcibly than the other two.

ε. *Pentatomic Acid Chlorides.*—Two only of these compounds are known, viz. PCl^5 and $SbCl^5$. They are both volatile, but the antimonic chloride suffers partial decomposition at the same time. To each of these chlorides there is a corresponding trichloride, and their general relations indicate that two of the chlorine-atoms are retained less forcibly than the other three.

With 1 at. of water, they yield hydrochloric acid and an oxychloride, *e.g.*:

$$PCl^5 + H^2O = 2HCl + PCl^3O,$$

but an excess of water likewise decomposes the oxychloride, forming hydrochloric acid and phosphoric or antimonic acid. Similar reactions are produced by alkalis, and in the case of pentachloride of phosphorus, by alcohols, the products being hydrochloric acid, a chloride of the alcohol-radicle, and either oxychloride of phosphorus or a phosphate of the radicle, according to the quantities present. Thus with phenylic alcohol:

$$PCl^5 + C^6H^5.H.O = C^6H^5.Cl + HCl + PCl^3O,$$

and

$$PCl^3O + 3(C^6H^5.H.O) = (C^6H^5)^3PO^4 + 3HCl.$$

With acids, or with salts of alkali-metal (acetate of sodium, for example) pentachloride of phosphorus yields oxychloride of phosphorus, hydrochloric acid, and a chloride of the acid radicle (pp. 898, 899), and in some cases, if a salt of the alkali-metal is present in excess, the corresponding anhydride is formed: thus

$$\underset{\text{Benzoate of sodium.}}{C^7H^5O.Na.O} + PCl^5 = PCl^3.O + NaCl + \underset{\text{Chloride of benzoyl.}}{C^7H^5O.Cl};$$

and

$$\underset{\text{Benzoate of sodium.}}{C^7H^5O.Na.O} + \underset{\text{Chloride of benzoyl}}{C^7H^5O.Cl} = NaCl + \underset{\text{Benzoic anhydride.}}{(C^7H^5O)^2O}.$$

CHLORINDATMITE. A product of the action of chlorine upon indigo (*q. v.*)

CHLORINDIN. See INDIN.

CHLORINE. *Symbol* Cl. *Atomic weight* 35·5. *Density* 35·5 (referred to hydrogen as unity.) *Atomic volume* 1.

Chlorine is a substance very widely distributed in nature. It exists chiefly in the form of chloride of sodium, which constitutes rock-salt when deposited in inland beds, sea-salt when dissolved in masses of water. The sea also contains chlorides of potassium, calcium, and magnesium. The chlorides of calcium, lead, mercury, and silver, respectively, form the partial or sole constituents of several well-known minerals, and free hydrochloric acid has been met with in the air of volcanic neighbourhoods. Chlorine was discovered by Scheele in 1774. Its elementary nature was first established by Davy in 1810.

1. Chlorine is usually prepared by the action of hydrochloric acid upon peroxide of manganese, at a gentle heat:

$$4HCl + Mn^2O^2 = 2H^2O + 2MnCl + Cl^2.$$

The liberated chlorine may be washed by transmission through a small quantity of water, and dried with oil of vitrol in the usual manner. It is best collected by downward displacement. It cannot be collected over mercury, on account of its rapid action on the metal. It cannot readily be collected over water, on account of solubility therein; but the difficulty may be obviated by evolving the gas rapidly, or by passing the delivery tube to the summit of the receiver, or by keeping the water in the trough perceptibly warm, or by saturating it with common salt. In the above reaction, the peroxide of manganese may be replaced by acid chromate of potassium; as also, though with questionable advantage, by several other oxidising agents, such as red or brown oxide of lead, chlorate of potassium, hypochlorite of calcium, nitric acid, &c. Moreover, a mixture of common salt and oil of vitrol, which generates hydrochloric acid abundantly, may be, and frequently is, substituted for the ready formed hydrochloric acid, thus:

$$2NaCl + 2H^2SO^4 + Mn^2O^2 = Na^2SO^4 + Mn^2SO^4 + 2H^2O + Cl^2.$$

This is the method usually adopted on the large scale, to generate chlorine for the manufacture of bleaching powder, chlorate of potassium, &c. It has the advantage of eliminating the whole of the chlorine from the chlorine-compound used, whereas, in the decomposition of the peroxide by hydrochloric acid alone, half the chlorine remains as protochloride of manganese. The sulphuric acid, when present in excess, has also the effect of drying the chlorine. The materials are mixed in a large alembic of nearly spherical form, and constructed either entirely of lead, surrounded at its lower part with a cast-iron steam-jacket, or of two hemispheres joined together in the middle, the upper being of lead, the lower of iron. In the former case the vessel is heated by steam, in the latter over a very gentle open fire. (See *Ure's Dictionary of Arts, Manufactures and Mines*, i. 666.)

Another method, which may be economically practised in sulphuric acid works, consists in heating a mixture of common salt and nitrate of sodium (Chili saltpetre) with excess of sulphuric acid. Hydrochloric and nitric acids are thereby evolved, and by their mutual action generate chlorine, peroxide of nitrogen and water:

$$HCl + HNO^3 = Cl + NO^2 + H^2O.$$

The mixed vapours are made to pass into condensers containing sulphuric acid, which absorbs the peroxide of nitrogen, forming a peculiar compound, which is afterwards used in the manufacture of sulphuric acid itself (see SULPHURIC ACID), while the chlorine passes on and may be used for the preparation of chlorates or hypochlorites. The residue of acid sulphate of sodium, left by the action of the sulphuric acid on the mixture of nitre and salt, remains liquid, and may be run off into a furnace and heated with an additional quantity of salt, producing hydrochloric acid and neutral sulphate of sodium, which last may be used in the manufacture of soda. (*Traité de Chimie générale, par Pelouze et Frémy*, 3^{me} éd. i. 414.)

2. Chlorine is also liberated by the simple action of a red heat upon certain chlorides, such as those of palladium, platinum, and gold, thus: $PtCl^2 = Pt + Cl^2$. Pentachloride of antimony, $SbCl^5$, breaks up, when gently heated, into trichloride of antimony, $SbCl^3$, and free chlorine, Cl^2; and in like manner, the trichloride of gold, $AuCl^3$, breaks up into protochloride of gold, $AuCl$, and free chlorine, Cl^2. Moreover, chlorine gas frequently results from the decomposition of its oxidised compounds.

Properties.—Chlorine has a yellowish-green colour, whence its name (χλωρος), and a pungent irritating smell. It is irrespirable unless very much diluted. It is one of the heaviest substances that are gaseous at common temperatures, being 35½ times heavier than hydrogen, and 2½ times heavier than atmospheric air. By a pressure of four atmospheres, at mean temperature 15·5° C., it is condensed into a yellow mobile liquid, having a specific gravity 1·33. It has resisted all attempts at solidification. At ordinary temperatures, water dissolves about twice its volume of chlorine, forming a solution which has the colour, smell, and general chemical properties of the gas. At low temperatures, water dissolves a still greater proportion of chlorine, and at the temperature 0° C. a definite hydrate of chlorine, $Cl.5H^2O$, crystallises out. If this hydrate be gently warmed in a sealed tube, it will, at a temperature of 38° C., decompose into a layer of water floating over a layer of liquid chlorine. This liquid chlorine may be readily distilled off, and condensed by means of a freezing mixture at the other extremity of the tube, which is usually bent for this purpose at an obtuse angle.

Chlorine possesses very active chemical properties, and gives origin to many phenomena of combination, substitution and indirect oxidation. It is moreover, non-inflammable, and does not unite directly with oxygen under any circumstances. At ordinary temperatures, chlorine combines directly with all the *metals*, with many metalloïds, such as *hydrogen* and *phosphorus*, and with many compound bodies, such as *sulphurous anhydride*, SO^2, *olefiant gas*, C^2H^4, *benzene*, C^6H^6, and *carbonic oxide*, CO. Its union with phosphorus, and with finely divided arsenic, antimony, tin, or copper, is attended with the phenomena of combustion. At increased temperatures, chlorine combines with many other substances, such as *sulphur*, *selenium*, *boron*, and *silicon*. It has not been made to combine directly with *carbon*. When ordinary combustible bodies containing carbon and hydrogen, such as paper, wood, wax-taper, &c., are ignited and immersed in a vessel of chlorine, the combustion continues chiefly at the expense of the hydrogen, which forms hydrochloric acid, while the carbon is deposited as a dense black smoke. Previous ignition of the hydrocarbonised substance is not always necessary to induce these phenomena. Paper dipped in oil of turpentine, $C^{10}H^{16}$, and plunged in a vessel of the gas, takes fire spontaneously, yielding abundance of hydrochloric acid and carbon.

Chlorine displaces *bromine*, *iodine*, and *fluorine*, from their combinations, by equivalent substitution. Free iodine strikes a deep blue colour with starch; and when starched paper dipped in iodide of potassium solution is brought into contact with chlorine, the iodine is liberated by the chlorine, and the characteristic blue iodide of starch produced: $KI + Cl = KCl + I$. Chlorine also displaces *hydrogen* by equivalent substitution, one half of the chlorine taking the place of an equivalent quantity of hydrogen, while the other half unites with the hydrogen eliminated:

$$\underset{\text{Salicin.}}{C^{13}H^{18}O^7} + Cl^2 = \underset{\text{Chloro salicin.}}{C^{13}H^{17}ClO^7} + HCl.$$

$$\underset{\text{Acetic acid.}}{C^2H^4O^2} + Cl^6 = \underset{\text{Trichloracetic acid.}}{C^2HCl^3O^2} + 3HCl.$$

Chlorine, by combining with hydrogen or a metal, acts indirectly as an oxidising agent. Thus, when chlorine-water is exposed to the action of sunlight, we have $Cl^2 + H^2O = 2HCl + O$. Again, when ferric hydrate, suspended in solution of hydrate of potassium, is treated with chlorine, we have produced ferric and hydrochloric acids, which react with the alkali to form potassium salts:

$$H^2O + \underset{\text{Ferric hydrate.}}{Fe^2H^3O^3} + Cl^3 = H^2O.Fe^2O^3, \ (i.e.\ \underset{\text{Ferric. acid.}}{H^2Fe^2O^4}) + 3HCl.$$

Chlorine destroys the colour of most organic pigments. This bleaching action is usually accompanied by oxidation and substitution, thus:

$$\underset{\text{Indigo.}}{C^8H^5NO} + H^2O + Cl^4 = \underset{\text{Chlorisatin.}}{C^8H^4ClNO^2} + 3HCl.$$

Chlorine also destroys odours of various kinds, and possibly infectious miasmata, either by abstracting hydrogen with or without substitution, or by indirectly oxidising.
W. O.

Antichloristic Theory.—Chlorine was originally regarded as a compound body, namely, *Oxygenised muriatic acid*, or *Oxymuriatic acid*. Muriatic acid was supposed to be a compound of oxygen with the unknown radicle *Muriaticum*, or *Murium*, and chlorine or oxygenised muriatic acid was supposed to contain the same radicle united with a larger quantity of oxygen. Moreover, as the driest muriatic acid, when brought in contact with red-hot metals, evolves a large quantity of hydrogen, and as 1 vol. of dry chlorine with 1 vol. of dry hydrogen forms 2 vols. of perfectly dry muriatic acid gas, it was concluded that 1 vol. of chlorine (or oxymuriatic acid), contains a half volume of oxygen, which, in the formation of muriatic acid gas, combines with 1 vol. of hydrogen; and that muriatic acid gas is an intimate compound, in equal numbers of atoms, of water, and a not yet isolated anhydrous muriatic acid, which may be called *hypothetical anhydrous muriatic acid*, to distinguish it from ordinary dry muriatic acid gas. Berzelius formerly arranged the various degrees of oxidation in the series as follows:

1 at. Murium=11·4 takes up of oxygen (=8)		and forms therewith	Antichloristic Names.	Chloristic Names.
2 at. = 16	. . .	27·4 pts. of	Hyp. anhyd. muriatic acid.	
3 „ = 24	. . .	35·4 „	Oxymuriatic acid.	Chlorine.
4 „ = 32	. . .	43·4 „	Euchlorine.	Hypochlorous anhydride.
6 „ = 48	. . .	59·4 „	?	Perchloric oxide.
8 „ = 64	. . .	75·4 „	Hyperoxymuriatic acid.	Chloric anhydride (hyp.)
10 „ = 80	. . .	91·4 „	?	Perchloric anhydride (hyp.)

It is easy to see that most of the phenomena exhibited by chlorine-compounds, may be rationally expressed in the language of this so-called "antichloristic theory." Muriatic acid gas is supposed to be a compound of 1 at. hypothetical anhydrous muriatic acid = 27·4 with 1 at. water = 9, making together 36·4 ($MuO^2.HO$).* Metallic chlorides are hypothetical anhydrous muriates of metallic oxides, $MuO^2.RO$, and may be formed, with evolution of hydrogen, by contact of a metal with muriatic acid gas, the oxidation of the metal being produced by the water. The same compounds are formed when a metal is immersed in oxymuriatic acid gas (MuO^3), the metal then taking away the third atom of oxygen of that gas, and forming an oxide, which unites with the remaining hypothetical anhydrous muriatic acid. The formation of a muriate and hyperoxymuriate (chlorate), when oxymuriatic acid comes in contact with the aqueous solution of an alkali, is effected by 5 at. of oxymuriatic acid giving up their third atom of oxygen to a sixth atom of the same acid, which is thereby converted into hyperoxymuriatic acid [$6MuO^3 + 6KO = KO.MuO^8 + 5(KO.MuO^2)$]. And in all cases in which chlorine is as an oxidising agent, where the one theory supposes that the element chlorine unites with hydrogen as a metal, and sets oxygen free, the other supposes that the third atom of oxygen in MuO^3, performs the same functions.

On the same theory, phosgene gas (oxychloride of carbon), is supposed to be a compound of hypothetical anhydrous muriatic acid with carbonic acid ($MuO^2.CO^2$); terchloride of phosphorus is a muriate of phosphorous acid, $PO^3.3MuO^2$, and the pentachloride is $PO^5.5MuO^2$, both compounds being formed by the combustion of phosphorus in the third atom of oxygen of MuO^3, whereby phosphorous or phosphoric acid is produced, which unites with the resulting MuO^2.

Such was the theory of the chlorine-compounds which maintained its ground till 1809. In that year, however, Gay-Lussac and Thénard showed, by arguments founded on numerous experiments, that the chemical relations of the so-called oxymuriatic acid, or chlorine, might all be explained on the supposition that it is an elementary substance, and this view was further carried out by Sir H. Davy in 1810, who first gave to this substance the name of CHLORINE. It is not necessary to go into all the arguments by which this view was ultimately established; it is sufficient to observe, that chlorine has never been shown to contain oxygen, or indeed to be capable in any way of resolution into simpler forms of matter, and therefore that its claim to the title of an element rests on the same foundation as that of the other bodies at present regarded as elementary. (For further details, see *Gmelin's Handbook*, ii. 356, and *Ure's Dictionary of Chemistry*, 4th edition, p. 318.)

---

* O = 8.

CHLORINE, DETECTION AND ESTIMATION OF. 1. *Reactions.*—Chlorine in the free state is recognised by its suffocating odour, its yellow-green colour, the bleaching action which it exerts on litmus, indigo, and other vegetable colours, and the deep blue colour which it produces with a mixture of starch and iodide of potassium. The aqueous solution exhibits the same characters.

Hydrochloric acid and solutions of metallic chlorides, either neutral or slightly acidulated with nitric acid, give with *nitrate of silver*, an immediate white curdy precipitate of chloride of silver, insoluble in hot nitric acid, easily soluble in ammonia; and with *mercurous nitrate*, a white curdy precipitate of mercurous chloride (calomel) insoluble in nitric acid and in ammonia, and turned black by ammonia. Both these reactions are extremely delicate. Solutions of chloride of sodium of various degrees of dilution, give with nitrate of silver and mercurous nitrate, the reactions indicated in the following table:

1 pt. chlorine in:	Nitrate of Silver.	Mercurous Nitrate.
100,000 pts. water	Slight turbidity.	Slight precipitate.
200,000 „ „	Immediate slight cloud.	Turbidity after a few minutes.
400,000 „ „	Very slight turbidity.	Very slight turbidity after some minutes.
800,000 „ „	Very faint opalescence.	Opalescence after some time.
1,600,000 „ „	Scarcely perceptible opalescence.	Scarcely perceptible opalescence after some time.

With solution of sal-ammoniac, the silver-solution behaves in a similar manner, and gives a perceptible cloud, even with 3,200,000 pts. of water; with the mercurous solution, the reaction ceases to be perceptible with 400,000 pts. of water to 1 pt. of chlorine. (Lassaigne, J. Chim. méd. viii. 518.)

The only salts which give with silver-solution a precipitate resembling the chloride, are bromides, iodides, and cyanides. Either of these salts is easily detected in presence of a chloride, viz. bromides and iodides by the colours of the bromine and iodine when set free, and by their reaction with starch-paste; cyanides by the formation of Prussian blue with ferroso-ferric salts; but the detection of small quantities of chlorine in presence of excess of either of the other salts, presents greater difficulty. Bromide, iodide, and cyanide of silver are all insoluble in cold nitric acid, and more or less soluble in ammonia. Iodine is, however, completely precipitated by nitrate of palladium, which does not precipitate chlorine: consequently the chlorine may be detected by adding nitrate of silver to the filtrate. The best mode of detecting a small quantity of a chloride in presence of excess of bromide, is to distil the dried salts with sulphuric acid and acid chromate of potassium, and pass the evolved red vapours into ammonia: if chlorine is present, chlorochromic acid will be evolved, and the liquid will be coloured yellow, from formation of chromate of ammonium; but if only bromine is present, it will remain colourless. Cyanide of silver dissolves with decomposition when boiled with strong nitric acid, and may thereby be separated from the chloride, which will remain undissolved.

As the greater number of metallic chlorides are soluble in water, the method of precipitation by nitrate of silver may be applied to them immediately. Cuprous chloride, and many oxychlorides which are insoluble in water, dissolve in nitric acid, and the chlorine contained in them may then be detected in the same manner. Oxygen-salts of chlorine, viz. the hypochlorites, chlorites, chlorates, and perchlorates, give off their oxygen when heated, and are reduced to chlorides: the reduction, excepting in the case of perchlorates, may also be effected by sulphurous acid. The chlorides of phosphorus and other non-metallic elements, are decomposed by water, yielding hydrochloric acid, in which the chlorine may then be detected by nitrate of silver. The chlorine in organic compounds is for the most part not immediately precipitated by nitrate of silver, only indeed when it may be said to exist as hydrochloric acid, namely, in combination with organic bases; from other organic compounds, as the chlorides of the alcohol- radicles, and the numerous class of compounds in which chlorine takes the place of hydrogen, it must first be separated, either by ignition with lime, or by heating the compound with nitric acid in a sealed tube (pp. 225, 247).

2. *Quantitative Estimation.*—Chlorine is always estimated as chloride of silver. If not present as hydrochloric acid or a metallic chloride, it must be reduced to that state by one of the methods just indicated. The solution is then slightly acidulated with nitric acid in the cold (the application of heat to the acid solution would drive off part of the chlorine); nitrate of silver is added in excess; and the

liquid either briskly agitated with the precipitate, or else left for some hours in a warm place, till the precipitate has completely settled down. The precipitate is collected on a filter, which should be as small as possible, washed with water, and dried at 100° C. It must then be separated as completely as possible from the filter, and introduced into a porcelain crucible previously weighed, the filter burnt to ashes outside the crucible, the ashes added to the contents of the crucible, and the whole strongly heated over a lamp till the chloride of silver is brought to a state of tranquil fusion, after which it is left to cool and weighed. It contains 24·74 per cent. chlorine. As a small portion of the chloride may be reduced by the organic matter of the filter during ignition, it is best, before weighing, to treat the cooled mass with a small quantity of nitric acid, in order to dissolve the reduced silver, then add hydrochloric acid, evaporate to dryness, fuse, and weigh. The quantity of chlorine introduced in this manner, will only be the equivalent of that which may have been lost by the previous reduction. The chloride of silver may also be collected on a weighed filter, and dried in an oil-bath at about 150° C.

The quantity of chlorine in a soluble chloride may also be estimated volumetrically, by precipitation with a standard silver-solution, a cubic centimetre of which contains 30·42 milligrammes of silver, corresponding to 10 milligrammes of chlorine.

Volumetric Estimation of Chlorine in Hypochlorites: CHLORIMETRY.—The value of the so-called "chlorides of lime, potash, and soda," which are mixtures of the hypochlorites, chlorides, and hydrates of the respective metals, depends upon the percentage of hypochlorite which they contain, or, what comes to the same thing, on the quantity of chlorine which they evolve when treated with an acid, thus:

$$2CaClO + H^2SO^4 = Ca^2SO^4 + H^2O + Cl^2$$

and this quantity may be conveniently estimated: *a.* By the quantity of *arsenious anhydride* which it will convert into arsenic anhydride in an acid solution: $As^2O^3 + Cl^4 + 2H^2O = As^2O^5 + 4HCl$.—*b.* By the quantity of *ferrous oxide* which it will convert into ferric oxide.—*c.* By the quantity of *iodine* which it will liberate from a standard solution of iodide of potassium.

a. 14 grammes of pure arsenious anhydride, dried at 100° C., are dissolved in caustic potash, and the solution is diluted to 1 litre; 1 cub. cent. of this solution contains 0·014 grm. As^2O^3, and requires for its conversion into arsenic anhydride, 0·010 grm. chlorine ($As^2O^3 = 198 : Cl^4 = 142 :: 14 : 10$).

Five grms. chloride of lime are triturated with water, the whole washed into a graduated cylinder and diluted to 100 c.c.; 50 c.c. of the arsenious solution are placed in a beaker, diluted with water, saturated with hydrochloric acid, and coloured blue by a drop of indigo-solution; and the solution of chloride of lime (well shaken up), is added from a burette, till the blue colour is nearly destroyed. A fresh drop of indigo is now to be added, and then the chlorine-solution again, very cautiously, and drop by drop, the contents of the beaker being continually agitated, till the colour finally disappears. This marks the end of the operation: for the decoloration of the indigo does not take place till all the arsenious anhydride is converted into arsenic anhydride. The percentage of available chlorine in the sample is then easily calculated. Suppose that 45 c.c. of the arsenious solution have been employed; these correspond to 0·45 grm. chlorine: consequently, the sample contains 9 per cent. of chlorine in the form of hypochlorite.

Another mode of proceeding is to act on a known volume of a standard *alkaline* solution of arsenious anhydride added in excess, and to estimate the excess by a standard solution of iodine (p. 266). This, according to Mohr, is the only accurate method.

b. A weighed quantity of the sample is made to act on a known quantity of ferrous sulphate added in excess, and the quantity of that salt unoxidised by the hypochlorite, is estimated by a standard solution of permanganate of potassium. Every 1 at. ferrous oxide converted into ferric oxide, corresponds to 1 at. chlorine:

$$2Fe^2O + Cl^2 + H^2O = Fe^4O^3 + 2HCl.$$

c. For the iodometric method, see ANALYSIS, VOLUMETRIC (p. 266. On CHLORIMETRY, see also *Ure's Dictionary of Arts, Manufactures and Mines*, i. 671).

3. *Separation of Chlorine from other Elements.*—The method of precipitation by nitrate of silver serves to separate chlorine from all other elements except bromine and iodine.

To estimate chlorine in presence of *bromine*, the two elements are precipitated together by nitrate of silver, the precipitate dried, ignited, and weighed in the manner just described (p. 904), and the bromine determined by the method given at page 678. From this the quantity of bromide of silver in the precipitate is found by the proportion Br : AgBr = 80 : 188; this deducted from the total weight of the precipitate, gives the quantity of chloride of silver therein; and 24·74 per cent. of this last quantity is the amount of chlorine sought.

The method of estimating chlorine in presence of *iodine* is precisely similar.

When chlorine, bromine, and iodine occur together, the iodine is first precipitated by nitrate of palladium (see IODINE), and in the filtrate the chlorine and bromine are determined as above. Or the three elements may be separated and estimated by Field's method (p. 678).

4. *Atomic Weight of Chlorine.*—The atomic weight of chlorine was determined by Berzelius (Ann. Ch. Phys. [2] xci. 102) in connection with those of silver and potassium; and the same method has been carried out, with very nearly accordant results, by Marignac (J. pr. Chem. xxxi. 272; Ann. Ch. Pharm. xliv. 14), Penny (Phil. Trans. 1839, p. 129), Maumené (Ann. Ch. Phys. [3] xviii. 41; Ann. Ch. Pharm. lx. 173), and, lastly, by Stas (*Recherches sur les Rapports réciproques des Poids atomiques*, Bruxelles, 1860). The series of operations is as follows:

1. Chlorate of potassium, $KClO^3$, when heated to redness, gives off all its oxygen, leaving chloride of potassium, whence the atomic weight of chloride of potassium compared with that of oxygen is known.

2. As 1 at. chloride of potassium throws down 1 at. of silver from its solutions, the determination of the quantity of chloride of silver precipitated by 1 at. chloride of potassium gives the atomic weight of chloride of silver, AgCl.

Or if a known weight of silver be dissolved in nitric acid, and the quantity of chloride of potassium required to precipitate it be determined, the ratio between the atomic weights of silver and chloride of potassium becomes known; whence also the atomic weight of chlorine may be found, by determining the weight of chloride of silver produced from a given quantity of silver.

3. The quantity of chloride of silver (c) produced from a given weight of silver (s) is found, either by igniting silver in chlorine gas, or by dissolving it in nitric acid and precipitating by hydrochloric acid: hence, the atomic weight of chloride of silver (w) being previously known, that of silver (x), is found by the proportion, $c : s = w : x$, and that of chlorine by difference; or, the atomic weight of silver being found from the quantity of chloride of potassium required to precipitate it, that of chlorine is calculated from the composition of the chloride as just determined.

1. *Determination of the Amount of Oxygen in Chlorate of Potassium.*—This may be determined either by heating the salt to redness, or else by reducing it with hydrochloric acid, evaporating to dryness, and igniting. In carrying out the former method, it is necessary to arrange the apparatus in such a manner that any small particles of the salt that may be carried away by the escaping gas may be collected and weighed.

The proportions of oxygen and chloride of potassium in 100 pts. of the chlorate, and the atomic weight of chloride of potassium thence determined, by the proportion $O^3 : KCl = 48 : x$, are as follows, according to the authorities above quoted:

	Berzelius.	Marignac.	Penny.	Maumené.	Stas.
O^3	39·150	39·161	39·177	39·209	39·154
KCl	60·850	60·839	60·823	60·791	60·846
	100·000	100·000	100·000	100·000	100·000
Atomic weight of KCl .	74·606	74·575	74·520	74·424	74·59

2. *Determination of the Atomic Weight of Chloride of Silver:*

100 pts. of chloride of potassium yielded, by precipitation with nitrate of silver:

	Berzelius.	Marignac.	Maumené.
Chloride of silver	192·4	192·35	192·75

100 pts. of silver dissolved in nitric acid, require of KCl for precipitation:

Marignac.	Stas.
69·062	69·103

Now 1 at. chloride of potassium precipitates 1 at. silver, forming 1 at. chloride of silver; hence, according to Marignac—

$$100 : 192{\cdot}35 = 74{\cdot}575 : AgCl = 143{\cdot}44.$$

3. By igniting 100 pts. of silver in chlorine gas, the following quantities of chloride of silver are obtained:

	Berzelius.	Marignac.		Penny.	Maumené.	Stas.
		(1844.)	(1845.)			
AgCl . .	132·75	132·73	132·84	132·84	132·73	132·845

Comparing now Marignac's first number, 132·73 (which agrees with that of Maumené and very nearly with that of Berzelius) with his determination of the atomic weight of chloride of silver above quoted, viz. 143·44, we find for the atomic weight of silver:

$$132{\cdot}73 : 143{\cdot}44 = 100 : Ag = 108{\cdot}06$$

whence: $Cl = 143{\cdot}44 - 108{\cdot}06 = 35{\cdot}38$

and: $K = 74{\cdot}575 - 35{\cdot}38 = 39{\cdot}19$

If, again, we start from the same atomic weight of KCl as before, viz. 74·575, and assume, according to Marignac's second determination (also that of Penny) that 100 pts. silver produce 132·84 pts. chloride; also that 100 pts. silver require for precipitation 69·062 KCl (Marignac), we arrive at the numbers in the left hand column of the following table; those in the right are found in like manner from the determinations of Stas:

Marignac.	Stas.
$Ag = \frac{100 \times 74{\cdot}575}{69{\cdot}062} = 107{\cdot}98$	$Ag = \frac{100 \times 74{\cdot}59}{69{\cdot}103} = 107{\cdot}94$
$Cl = \frac{107{\cdot}98 \times 32{\cdot}84}{100} = 35{\cdot}46$	$Cl = \frac{107{\cdot}94 \times 32{\cdot}845}{100} = 35{\cdot}45$
$K = 74{\cdot}575 - 35{\cdot}46 = 39{\cdot}12$	$K = 74{\cdot}59 - 35{\cdot}45 = 39{\cdot}14$

Dumas (Ann. Ch. Pharm. cxiii. 21), by igniting silver in chlorine gas, found that:

9·954 grm. silver gave 13·227 AgCl
19·976 „ „ 26·542 „

whence, taking the atomic weight of silver at 108 (a result deduced from the analyses of the nitrate by Marignac):

The first determination gives Cl = 35·512
The second „ „ Cl = 35·499
Mean = 35·5

This number 35·5, being also very near to the results above detailed, is generally adopted.

CHLORINE, HYDRATE OF. $Cl.5H^2O$.—When water is introduced into a vessel filled with chlorine, in quantity not exceeding 5 at. water to 1 at. chlorine, and the vessel is exposed for some days to a freezing temperature, a pale yellow translucent hydrate is formed, sometimes in arborescent crystalline masses, sometimes in needles and rhombic octahedrons. It may be sublimed from one part of the vessel to another. When gently heated in an open vessel, it is resolved into chlorine gas and aqueous solution of chlorine. At 38° C. in a sealed tube, it is resolved into aqueous chlorine and free liquid chlorine, which separates as a distinct stratum. The hydrate acts on ammonia, ammoniacal salts, and alcohol in the same manner as gaseous chlorine. (Faraday, *Quarterly Journal of Science*, xv. 71.)

CHLORINE, OXIDES, and **OXYGEN-ACIDS OF.** Chlorine forms four oxygen-acids, all of which may be regarded as oxides of hydrochloric acid, namely:

Hypochlorous acid	$HClO$	Chloric acid	$HClO^3$
Chlorous acid	$HClO^2$	Perchloric acid	$HClO^4$

They are obtained by the following processes:

1. Hypochlorous acid, $HClO$, is produced by oxidising hydrochloric acid with permanganic acid; and hypochlorite of potassium is formed, together with chloride, by passing chlorine into a cold solution of potash:

$$KHO + Cl^2 = KClO + KCl.$$

2. Solution of hypochlorous acid, $HClO$, especially at increased temperatures, is converted spontaneously into chloric acid, $HClO^3$, together with water, chlorine, and oxygen. Moreover the solution of an alkaline hypochlorite, when boiled for some time, breaks up into chlorate and chloride: $3KClO = KClO^3 + 2KCl$.

3. Chloric acid, $HClO^3$, when deoxidated by nitrous acid, yields chlorous acid, $HClO^2$; and conversely, chlorous acid, by its spontaneous decomposition, yields chloric acid and other products.

4. Chloric acid, $HClO^3$, when oxidated at the positive pole of a voltaic battery, yields perchloric acid, $HClO^4$. Moreover chlorate of potassium, when moderately heated, breaks up into perchlorate of potassium, chloride of potassium, and oxygen.

Hypochlorites, chlorites, chlorates, and perchlorates of alkali-metal, when strongly heated, are alike converted into chlorides by loss of oxygen.

The anhydride of a monobasic oxygen-acid is formed from two atoms of the acid by the loss of one atom of water. The chlorine-acids should therefore yield the following anhydrides:

Acids.		Anhydrides.	
$2HClO$	$- H^2O =$	Cl^2O	Hypochlorous
$2HClO^2$	$- H^2O =$	Cl^2O^3	Chlorous
$2HClO^3$	$- H^2O =$	Cl^2O^5	Chloric
$2HClO^4$	$- H^2O =$	Cl^2O^7	Perchloric

The first two anhydrides are tolerably well known, the last two have not yet been obtained. We are, however, acquainted with the corresponding iodic and periodic anhydrides, I^2O^5 and I^2O^7, respectively. By the reabsorption of an atom of water, one atom of each anhydride is reconverted into two atoms of the corresponding acid

$$Cl^2O + H^2O = 2HClO$$
$$Cl^2O^3 + H^2O = 2HClO^2$$
$$(I^2O^5 \text{ or}) \; Cl^2O^5 + H^2O = 2HClO^3 \; (\text{or } 2HIO^3)$$
$$(I^2O^7 \text{ or}) \; Cl^2O^7 + H^2O = 2HClO^4 \; (\text{or } 2HIO^4)$$

In addition to the above anhydrides, a complete series of chlorine-oxides should obviously include three other terms, thus:

Cl^2	Chlorine	Cl^2O^4	Perchloric oxide
Cl^2O	Hypochlorous anhydride	Cl^2O^5	Chloric anhydride
Cl^2O^2	Chloric oxide ?	Cl^2O^6	Hyperchloric oxide ?
Cl^2O^3	Chlorous anhydride	Cl^2O^7	Perchloric anhydride

Soubeiran obtained from euchlorine (p. 913) a gas which decomposed into equal volumes of chlorine and oxygen, a result considered by Berzelius to be conclusive of the existence of chloric oxide. Hyperchloric oxide is not improbably identical with Millon's perchloro-chloric acid, Cl^6O^{17}, or $3Cl^2O^6$ (?) Perchloric oxide is a very well-known substance, which, moreover, appears to be identical with Millon's chloro-chloric acid, Cl^6O^{13}, or $3Cl^2O^4$ (?) Perchloric oxide is decomposed by water into chlorous and chloric acids:

$$Cl^2O^4 + H^2O = HClO^2 + HClO^3.$$

Hypochlorous Anhydride, Acid, and Salts.

HYPOCHLOROUS ANHYDRIDE. Cl^2O.—This gas, which was discovered by Balard in 1834 (Ann. Ch. Phys. [2] lvii. 225), may be prepared: 1. By adding glacial phosphoric acid to a concentrated solution of hypochlorous acid standing over mercury. The glacial phosphoric acid abstracts water from the hypochlorous acid, and the gaseous anhydride thus produced collects in the upper part of the tube: $2HClO - H^2O = Cl^2O$.

2. By passing chlorine gas over mercuric oxide contained in a tube kept cool by ice:

$$Hg^2O + Cl^4 = Cl^2O + 2HgCl.$$

The mercuric oxide should be prepared by precipitation, and dried at a somewhat high temperature, 300° C. Any excess of mercuric oxide remains combined with the resulting mercuric chloride in the form of a brown crystalline oxychloride. The gas may be collected by downward displacement, or in the mercurial trough, but it cannot be kept long over mercury, as it gradually acts upon the metal.

Hypochlorous anhydride is a gas of a pale reddish-yellow colour, and a powerful odour somewhat resembling that of chlorine. Its specific gravity does not appear to have been determined experimentally. By calculation, supposing the molecule to occupy two volumes, it is $\frac{2 \times 35{\cdot}5 + 16}{2} = 43{\cdot}5$, referred to hydrogen, and 3·015 referred to air as unity. It is so readily decomposed into two volumes of chlorine and one volume of oxygen, that it cannot be preserved unchanged, even for a few hours. By a slight elevation of temperature, or sometimes spontaneously, decomposition takes place with explosion. In sunlight the decomposition is very rapid, but usually tranquil. At the low temperature produced by a mixture of salt and ice, the gas is condensed into a deep orange-coloured liquid, heavier than water, and very explosive. Both the gaseous and liquid anhydride dissolve in water, undergoing decomposition and being converted into hypochlorous acid:

$$Cl^2O + H^2O = 2HClO.$$

The general reactions of the anhydride correspond with those of the acid, but are more violent.

HYPOCHLOROUS ACID. $HClO$.—This acid may be prepared:

1. From the anhydride, as just mentioned.
2. By passing air saturated with hydrochloric acid through a solution of perman-

ganate of potassium, acidulated with sulphuric acid and heated in a water bath. The distillate is a solution of hypochlorous acid formed by the direct oxidation of hydrochloric acid: $HCl + O = HClO$.

3. By the addition of almost any oxacid to a metallic hypochlorite.

4. By passing chlorine gas into water, holding suspended or dissolved certain metallic oxides, hydrates, carbonates, sulphates, phosphates, &c. In practice, oxide of mercury, and, according to Williamson, carbonate of calcium, are found to be the most advantageous. Either of these substances is to be agitated with water and treated with chlorine gas:

$$Ca^2CO^3 + H^2O + Cl^4 = CO^2 + 2HClO + 2CaCl.$$

The product of the action is to be distilled off, and if necessary concentrated by one or two redistillations of the most volatile distillates.

Aqueous hypochlorous acid has a yellowish colour, an acrid taste, and a characteristic sweet chloroïd smell. The strong acid decomposes rapidly, even when kept in ice. The dilute acid is more stable, but is decomposed by long boiling into chloric acid, water, chlorine, and oxygen. Hypochlorous acid, like chlorine, possesses powerful bleaching properties. Moreover, chloro-derivatives may be produced by its agency, thus:

$$\underset{\text{Benzene.}}{C^6H^6} + HClO = \underset{\text{Chlorobenzene.}}{C^6H^5Cl} + H^2O.$$

Hydrochloric acid decomposes hypochlorous acid, with formation of chlorine:

$$HClO + HCl = H^2O + Cl^2.$$

Hypochlorous acid is a very powerful oxidising agent. It rapidly converts many of the elements, iodine, selenium, and arsenic, for instance, into their highest oxides, at the same time liberating chlorine. The metals differ much from one another in the nature of their respective reactions with hypochlorous acid. Those which decompose the acid form oxides, as does iron, or oxychlorides, as do copper and mercury. Silver, indeed, forms a chloride and liberates oxygen, thus:

$$Ag^2 + 2HClO = 2AgCl + H^2O + O.$$

Many metallic oxides, those of manganese, cobalt, and lead, for example, are peroxidised, with liberation of chlorine; but oxide of silver is converted into chloride of silver, with liberation of oxygen:

$$Ag^2O + 2HClO = 2AgCl + H^2O + O^2.$$

HYPOCHLORITES.—1. Pure hypochlorites are made by neutralising hypochlorous acid with hydrates, such, for instance, as those of sodium, potassium, calcium, barium, magnesium, zinc, copper, &c.—2. Hypochlorites are usually prepared by passing chlorine gas into solutions of hydrated or carbonated alkali, or over the dry hydrates of the earths. By this process, a chloride and a hypochlorite are simultaneously produced. The reaction is believed to be as follows:

$$Cl^2 + 2CaHO = CaCl + CaClO + H^2O.$$

These mixed compounds constitute the bleaching and disinfecting salts of commerce, the properties of which were known as early as the time of Berthollet. They were long regarded as chlorides of the alkali- and earth-metals, and known as *chloride of lime*, *chloride of soda*, &c., till Berzelius suggested the idea that they might be mixtures of metallic chlorides with alkaline chlorites ($M^2O.Cl^2O^3$). Balard, in 1834, showed that their properties are best explained by regarding them as mixtures of chlorides and hypochlorites. The only objections to this view are that alcohol does not extract chloride of calcium from bleaching powder, as we should *à priori* expect, and, unlike mixtures containing chloride of calcium, bleaching powder is not deliquescent. These anomalies may possibly be due to the formation of a double salt, containing chloride and hypochlorite of calcium in chemical combination with one another.

The pure hypochlorites, when acted upon by sulphuric acid, or even by carbonic acid, liberate hypochlorous acid, thus:

$$2CaClO + H^2SO^4 = 2HClO + Ca^2SO^4.$$

The mixed salts behave in the same manner, provided the sulphuric acid is not in excess; but otherwise chlorine, and not hypochlorous acid, is evolved:

$$CaClO + CaCl + H^2SO^4 = H^2O + Cl^2 + Ca^2SO^4.$$

The sulphuric acid acts first upon the hypochlorite to liberate hypochlorous acid, and then upon the chloride to liberate hydrochloric acid, the co-existence of which two acids cannot occur, owing to their mutual decomposition into water and free chlorine, as we have already seen. Hydrochloric acid can liberate hypochlorous acid from the pure or mixed salts, thus: $NaClO + HCl = HClO + NaCl$. But any excess of hydrochloric acid immediately reacts upon the nascent hypochlorous acid to form water and chlorine. Solutions of the hypochlorites, either pure or commercial, are very unstable, but are more permanent in the presence of free alkali. They gradually give off oxygen gas, and finally yield mixtures of chloride and chlorate. Their decomposition takes place very definitely at a boiling temperature, thus:

$$3CaClO = CaClO^3 + 2CaCl.$$

Of themselves they act as bleaching agents, probably by evolution of oxygen; but the effects produced by acidifying their solutions, and thereby liberating hypochlorous acid, are much more rapid. With most metallic oxides and salts, the hypochlorites react as does hypochlorous acid upon the oxides. They convert oxide of silver, for instance, into chloride of silver, with liberation of oxygen:

$$Ag^2O + 2NaClO + H^2O = 2AgCl + 2NaHO + O^2;$$

and sulphate of manganese into hydrated peroxide of manganese, with liberation of chlorine:

$$Mn^2SO^4 + 2NaClO + H^2O = Na^2SO^4 + 2MnHO^2 + Cl^2.$$

The characters of the individual salts will be described in a distinct article (HYPOCHLORITES). For the valuation of hypochlorites see p. 904.

Chlorous Anhydride, Acid, and Salts.

CHLOROUS ANHYDRIDE. Cl^2O^3.—This gas, discovered by Millon (Ann. Ch. Pharm. xlvi. 298), results from the spontaneous decomposition of chlorous acid, which is a somewhat ill-defined and unstable substance:

$$2HClO^2 = H^2O + Cl^2O^3.$$

It is also produced by the reaction of chloric acid with nitrous acid or anhydride:

$$2HNO^2 + 2HClO^3 = 2HNO^3 + H^2O + Cl^2O^3.$$

Instead of preformed chloric acid and nitrous acid or anhydride, a mixture of chlorate of potassium, nitric acid, and arsenious anhydride is usually employed. The nitric acid is first reduced by the arsenious anhydride to the state of nitrous acid, which is the real deoxygenant of the liberated chloric acid:

$$As^2O^3 + 2H^2O + 2KClO^3 = 2KH^2AsO^4 + Cl^2O^3.$$

The reaction is effected by the application of a very gentle heat. The arsenious anhydride may be replaced by tartaric acid or other deoxidising agent. The gas must be collected by displacement.

Chlorous anhydride is a yellowish green gas, permanent in a freezing mixture of ice and salt, but liquefiable by extreme cold. Its specific gravity, calculated for a condensation to 2 vols., is $\frac{71 + 48}{2} = 59{\cdot}5$ referred to hydrogen, and 4·123 referred to air. At slightly elevated temperatures, 57° C. and upwards, it is decomposed, with explosion, into chlorine and oxygen. It dissolves freely in water or in solutions of the alkaline and earth-alkaline hydrates, gradually forming chlorous acid or chlorites.

CHLOROUS ACID. $HClO^2$.—This acid may be prepared by condensing chlorous anhydride in water:

$$Cl^2O^3 + H^2O = 2HClO^2.$$

or by acting upon a chlorite with some diluted acid, such as sulphuric or phosphoric:

$$2PbClO^2 + H^2SO^4 = 2HClO^2 + Pb^2SO^4.$$

The acid, or its concentrated solution, is a greenish yellow liquid of great tinctorial power, and having strong bleaching and oxidising properties. It does not decompose carbonates, but reacts slowly with caustic alkalis and earths to form chlorites.

CHLORITES. $MClO^2$.—The alkaline and earthy chlorites are formed as above described. They also result from the action of perchloric oxide on bases (p. 912). They are, for the most part, soluble, crystallisable, colourless salts, possessed of bleaching properties. The insoluble chlorites of silver, lead, and other metals are produced by double decomposition:

$$AgNO^3 + KClO^2 = KNO^3 + AgClO^2.$$

The chlorites are decomposed even by carbonic acid.

For the characters of the individual chlorites, see page 914.

Chloric Acid and Salts.

Chloric Acid. $HClO^3$. (Vauquelin, Ann. Chim. xcv. 91; Serullas, Ann. Ch. Phys. [2] xlv. 204, 270.)—1. The acid is liberated from chlorates by the addition of a stronger acid. It is found advantageous to use equivalent quantities of chlorate of barium and sulphuric acid:

$$2BaClO^3 + H^2SO^4 = 2HClO^3 + Ba^2SO^4.$$

The solution of chloric acid is separated from the insoluble sulphate of barium by filtration, and concentrated by evaporation in vacuo.—2. This acid also results from the spontaneous decomposition of solutions of hypochlorous acid, chlorous acid, and peroxide of chlorine.

Chloric acid is a colourless syrupy liquid, having a strong acid reaction, and when warm, a pungent chloroïd smell. It is decomposed by organic matter, with charring, and frequently even with ignition. It is somewhat unstable at ordinary temperatures. At 40° C. it undergoes marked decomposition, and at a boiling heat is rapidly converted into perchloric acid, water, chlorine, and oxygen. It is a very powerful oxidising and bleaching agent. It is decomposed by hydrochloric, sulphydric, and sulphurous acids, with liberation of chlorine.

Chlorates. $MClO^3$.—1. These salts may be prepared by saturating the acid with bases. Chlorate of barium is usually made by this process (p. 885).

2. Zinc, and one or two other metals, dissolve in chloric acid to form chlorates, thus: $HClO^3 + Zn = ZnClO^3 + H$; but a part of the acid always undergoes a more complex decomposition.

3. Alkaline chlorates are produced by boiling solutions of the hypochlorites, or, what comes to the same thing, by passing chlorine into caustic or carbonated alkali, and boiling the resulting liquid: $3KClO = KClO^3 + 2KCl$. The chlorate is separated from the chloride by crystallisation.

The chlorates are chiefly interesting as sources of oxygen gas. Chlorate of potassium and most chlorates are decomposed by heat into chloride and oxygen, thus, $KClO^3 = KCl + O^3$; but the chlorates of the earth-metals yield oxygen, chlorine, and metallic oxide: $2MgClO^3 = Mg^2O + Cl^2 + O^5$. Prior to the ultimate decomposition of chlorate of potassium, a portion of perchlorate is produced. The fused chlorates are powerful oxidising agents. Mixtures of chlorate with combustible substances, such as sulphur, sulphide of antimony, and sugar, explode violently on the application of heat, or by percussion. Strong sulphuric acid liberates perchloric oxide from the chlorates, and, by its action on mixtures of chlorate with combustible matters, frequently induces combustion. Nitric acid reacts with chlorate of potassium to form nitrate of potassium, perchlorate of potassium, and free chlorine and oxygen gases. Hydrochloric acid produces euchlorine, which is a gaseous mixture of chlorine and perchloric oxide. A mixture of chlorate of potassium and hydrochloric acid is much used for oxidising mineral and organic compounds. All the chlorates are soluble in water, and hence do not precipitate the salts of the heavy metals. Chlorate of potassium, the most important member of the class, is one of the least soluble. Unlike the hypochlorites and the chlorites, the chlorates do not bleach until after the addition of an acid. [For the description of the individual salts, see pp. 885—890].

Perchloric Acid and Salts.

Perchloric Acid. $HClO^4$.—This acid was discovered in 1815 by Count Stadion (Gilb. Ann. lii. 197), afterwards more particularly examined by Serullas (Ann. Ch. Phys. [2] xlv. 270; xlvi. 294, 323), and quite recently by Roscoe[*], who has obtained it in definite form. It is produced: 1. By the electrolysis of chloric acid. Oxygen and chlorine are evolved in small quantities at the positive pole, and hydrogen at the negative pole; but the greater part of the oxygen remains in the liquid, and converts the chloric into perchloric acid (Stadion).—2. By the distillation of chloric acid (p. 910).—3. By the action of sulphuric acid upon chlorate of potassium (see Perchloric Oxide, p. 912).—4. By the action of certain acids upon the perchlorates. Thus, fluosilicic may be added to perchlorate of potassium, and the resulting insoluble fluosilicate of potassium filtered off from the solution of perchloric acid; or sulphuric instead of fluosilicic acid may be employed, and the volatile perchloric acid distilled off from the sulphate of potassium. (Serullas.)

Aqueous perchloric acid obtained by either of these methods may be concentrated by boiling till it attains a temperature of 203° C., after which it passes over unchanged in the form of an oily liquid containing 70·3 per cent., $HClO^4$. If this oily acid be

---

[*] These results, which are not yet published, have been kindly communicated by Professor Roscoe.

distilled with twice its volume of strong sulphuric acid, it gives up its water to the latter, and perchloric acid passes over nearly pure in the form of a yellowish strongly fuming liquid. On continuing the distillation, the oily acid above-mentioned begins to pass over; but as soon as it comes in contact with the more volatile portion of the distillate, the two unite into a crystalline mass consisting of a hydrate, $HClO^4.H^2O$. Both these products are, however, contaminated with sulphuric acid mechanically carried over. To obtain the volatile liquid in a pure state, the crystals must be redistilled *per se*. They then split up into pure perchloric acid, $HClO^4$, which is obtained as the first produce of the distillation, and the oily acid, which contains a larger proportion of water, and passes over afterwards. (Roscoe.)

Pure perchloric acid, $HClO^4$, is a colourless very volatile liquid, having a specific gravity of 1·782 at 15·5 C. Its vapour is likewise colourless and transparent, but on coming in contact with the air, it absorbs water, and forms dense white fumes. Perchloric acid in this state is one of the most powerful oxidising agents known; a single drop brought in contact with charcoal, paper, wood, or other organic substance, immediately causes an explosive combustion, which in violence does not fall far short of the sudden decomposition of chloride of nitrogen. The acid unites also very energetically with water, a violent hissing noise being produced. The greatest care must be taken in working with this substance, as one drop falling on the skin produces cauterisation, and leaves a wound which does not heal for months. Like pure nitric acid, this acid cannot be distilled by itself without undergoing decomposition, a singular black explosive body being produced when it is boiled. It likewise undergoes spontaneous decomposition at the ordinary temperature, the bulbs in which it was sealed exploding even when kept in the dark.

The composition of pure perchloric acid was determined by neutralising it with carbonate of potassium, adding acetic acid to acid reaction, evaporating to dryness, throwing the perchlorate of potassium on a weighed filter, washing out the soluble acetate with absolute alcohol, and determining the composition of the potassium salt thus produced. In this manner results agreeing closely with the theory were obtained. Thus, 1·2185 grm. of acid gave 1·6785 of potassium salt, calculation requiring 1·6876. Of this salt, 0·966 grm. heated with peroxide of iron lost 0·444 grm., and the residual KCl required 0·744 grm. pure silver for complete precipitation. Now 0·744 Ag is equivalent to 0·513 KCl, and by calculation 0·966 $KClO^4$ should yield 0·519 KCl. (Roscoe.)

The *Hydrate*, $HClO^4.H^2O$ (containing 84·81 per cent. $HClO^4$), is obtained in the pure state by adding water to the pure acid $HClO^4$. It is a white, solid, crystalline substance, which melts at 50° C., and undergoes decomposition when heated to 110°, splitting up into the pure acid and an aqueous oily acid. Its composition was determined by the method adopted in the case of the pure acid. The specific gravity of the liquid hydrate at 50° C. is 1·811. Although not so violent in its action on organic matter as the pure acid, the fused hydrate when brought into contact with paper or wood, induces immediate combustion, and when dropped into water, combines therewith making a hissing noise.

When it is distilled, the temperature is found to rise gradually to 203° C., at which point it remains constant, a heavy oily liquid then passing over, which in outward appearance cannot be distinguished from sulphuric acid. This acid contains 72·1 per cent. of $HClO^4$, and does not therefore correspond to any definite hydrate, $HClO^4.2H^2O$ requiring 73·6 per cent. $HClO^4$, and $HClO^4.3H^2O$, requiring 65·05 per cent. $HClO^4$. If aqueous perchloric acid be concentrated by boiling, water goes off, and the temperature rises to 200° C., when the acid is likewise found to contain 72·1 per cent. of $HClO^4$. Hence an aqueous acid loses water, and the crystallised hydrate loses perchloric acid on boiling under the ordinary atmospheric pressure, until both arrive at a point when no further change takes place, and an acid containing 72·1 per cent. $HClO^4$ passes off unchanged. (Roscoe.)

Aqueous perchloric acid reddens litmus strongly, but does not bleach. It dissolves zinc and iron, with evolution of hydrogen, forming perchlorates. When dilute, it is unaffected by sulphydric and sulphurous acids, which reduce all other oxacids of chlorine.

PERCHLORATES.—These salts are produced: 1. By the reaction of perchloric acid with metals, oxides, sulphides, or carbonates, or of perchlorate of barium with sulphates, thus:

$$HClO^4 + BaHO = BaClO^4 + H^2O$$
$$2BaClO^4 + Na^2SO^4 = 2NaClO^4 + Ba^2SO^4.$$

2. By the decomposition of chlorates. During the decomposition of chlorate of potassium by heat, and after a considerable evolution of oxygen has taken place, the previously fused salt is observed to assume a pasty condition, and if the heat be then discontinued, the residue will be found to consist principally of perchlorate and chloride of potassium,

which two salts may be separated from one another by solution and crystallisation, the perchlorate being much the less soluble:

$$2KClO^3 = KClO^4 + KCl + O^2.$$

Or, the chlorate of potassium may be decomposed by nitric acid:

$$3KClO^3 + 2HNO^3 = KClO^4 + 2KNO^3 + H^2O + Cl^2 + O^4,$$

and the resulting nitrate and perchlorate of potassium separated by crystallisation.

Perchlorate of potassium is sparingly soluble in cold water; but the perchlorates in general are soluble, crystalline, deliquescent salts. They deflagrate, though less violently than the chlorates, when thrown on ignited charcoal. They require a stronger heat than do the chlorates to effect their decomposition into chloride and oxygen. Sulphuric acid liberates perchloric acid from the perchlorates, but not until the temperature rises to 100° C.: other acids liberate perchloric acid, only when they form insoluble salts with the bases of the perchlorates. Hence, unlike chlorates, the perchlorates do not assume a yellow colour when acted upon by sulphuric or hydrochloric acid. [For the description of the individual salts, see PERCHLORATES.]

Perchloric Oxide and Euchlorine.

PERCHLORIC OXIDE. Cl^2O^4.—This very explosive compound, which was discovered by Count Stadion (*loc. cit.*), may be prepared by the action of strong sulphuric acid upon chlorate of potassium, whereby perchlorate of potassium, acid sulphate of potassium, water, and perchloric oxide are produced:

$$3KClO^3 + 2H^2SO^4 = KClO^4 + 2KHSO^4 + H^2O + Cl^2O^4.$$

The chlorate should be purified by recrystallisation, fused after drying, at the lowest adequate temperature, and then finely pulverised. The powder must be added little by little to sulphuric acid, made cool by a mixture of ice and salt, until a pasty mass is produced. This is to be set aside for some time, and afterwards, by means of a water-bath, to be very gently heated in a retort. The evolved gaseous perchloric oxide must be collected by downward displacement. Calvert has shown that perchloric oxide, mixed with carbonic acid, may be readily obtained by heating finely powdered chlorate of potassium with crystallised oxalic acid to a temperature of 70° C. (p. 888).

Perchloric oxide is a gas of a bright yellow colour, and sweet aromatic smell. At the low temperature produced by a mixture of salt and ice, it is condensed into a yellowish highly explosive liquid. Faraday succeeded in solidifying it by means of the intense cold produced by the evaporation of solid carbonic acid and ether. In daylight the gas undergoes spontaneous decomposition into chlorine and oxygen. This decomposition is frequently, and, when induced by elevation of temperature, almost invariably, attended by a violent explosion. The contact of highly combustible matters also determines an explosion. Liquid perchloric oxide unites with water at a temperature of 0° C., to form a solid hydrate. At ordinary temperatures, water dissolves several times its volume of the gas. The solution has a yellow colour, is devoid of acid reaction, bleaches powerfully, and is very unstable, being decomposed into chloric acid, chlorous acid, and other products. Perchloric oxide is absorbed by alkaline solutions, with formation of chlorate and chlorite:

$$2KHO + Cl^2O^4 = KClO^3 + KClO^2 + H^2O.$$

The molecule of perchloric oxide Cl^2O^4, like the molecule of chlorine Cl^2, seems to be binary or dyadic, and to halve itself in the act of combination. In this manner, the correlations of chlorite and chlorate would correspond with those of chloride and hypochlorite, thus:

$$\text{Chloride}\ \left.\begin{matrix}H\\Cl\end{matrix}\right\}\quad \text{Hypochlorite}\ \left.\begin{matrix}H\\Cl\end{matrix}\right\}O.\quad \text{Chlorite}\ \left.\begin{matrix}H\\ClO^2\end{matrix}\right\}\quad \text{Chlorate}\ \left.\begin{matrix}H\\ClO^2\end{matrix}\right\}O.$$

EUCHLORINE.—When chlorate of potassium is acted upon by hydrochloric acid, a bright yellow gas, called euchlorine, is liberated. This gas contains chlorine and oxygen in the same proportions as hypochlorous anhydride, Cl^2O, but despite its uniformity of composition, it is evidently a mixture, probably of chlorine and perchloric oxide. The following equation is believed to express its formation correctly:

$$4KClO^3 + 12HCl = 4KCl + 6H^2O + (9Cl + 3ClO^2).$$

This mixed gas has a sweet aromatic smell, and powerful bleaching properties. By passing it through a U-tube immersed in a mixture of salt and ice, the perchloric oxide is separated in the liquid state from the free uncondensed chlorine. According to Millon, the liquid perchloric oxide obtained by cooling euchlorine, differs from the liquid perchloric oxide obtained by means of sulphuric acid and chlorate of potassium, in its somewhat greater stability, in its somewhat higher boiling point, and in the circumstance that, although, like the normal compound, it is decomposed by alkalis into chlorate and chlorite, yet that, unlike the normal compound, it yields two equivalents of the former for one of the latter salt. Hence Millon assigns to it the formula $Cl^6O^{13} = 3Cl^2O^4$?

$$Cl^6O^{13} + 6KHO = 3H^2O + 4KClO^3 + 2KClO^2,$$

but these differences may probably be due to differences in the purity of these two bodies. Moreover, perchloric oxide is a very difficult subject to investigate, and the descriptions of different experimentalists vary considerably from one another. (See *Gmelin's Handbook*, ii. 304, 310.) W. O.

CHLORINE, SULPHIDES OF. Two only of these compounds are known in the free state, viz. SCl and SCl^2. The former is analogous in composition to hypochlorous anhydride, ClO, but exhibits no analogy whatever to that compound in its properties. It is doubtful indeed whether the sulphur or the chlorine in these compounds is the negative element; but they are usually regarded as *chlorides of sulphur*, and as such will be more fully considered. (See SULPHUR.)

Similar observations apply to the compounds of chlorine and selenium.

CHLORIODOFORM. *Dichlorinated Iodide of Methyl.* $CHCl^2I$. (Serullas, Ann. Ch. Phys. [2] xxv. 314; xxxix. 225.—Mitscherlich, Pogg. Ann. xi. 164.—Bouchardat, Ann. Ch. Pharm. xxii. 2229.—Gm. vii. 337). This compound was discovered by Serullas in 1824, but its composition was first correctly ascertained by Bouchardat. It is obtained by distilling iodoform with an equal weight of pentachloride of phosphorus or mercuric chloride. The materials are intimately mixed, and distilled in a retort; the dark red distillate is decolorised with aqueous potash, then shaken up with strong sulphuric acid, to free it from chloride of ethylene, afterwards separated from the sulphuric acid by a tap-funnel, and purified by rectification.

Chloriodoform is a transparent pale yellow liquid of specific gravity 1·96, having an aromatic odour and saccharine taste, and becoming rose-coloured by exposure to the air. It remains fluid at the lowest temperatures, and is not decomposed by distillation. It is but sparingly soluble in water. Heated with strong aqueous potash, or with alcoholic potash, it yields formate, chloride, and iodide of potassium:

$$CHCl^2I + 2K^2O = CHKO^2 + 2KCl + KI.$$

In contact with chlorine gas, it solidifies and yields trichloride of iodine.

CHLORISATIC ACID. See ISATIC ACID.

CHLORISATYDE and **CHLORISATYDIC ACID.** See ISATYDE and ISATIC ACID.

CHLORISATIN. See ISATIN.

CHLORISATOSULPHITES. See ISATOSULPHITES.

CHLORITE. *Leuchtenbergite, Pennine.*—This name is applied to certain silicates of magnesia and alumina occurring in plutonic formations, and forming the characteristic ingredients of chlorite slate. It formerly included ripidolite and clinochlore, and is still applied to at least two minerals, differing in crystalline form, and somewhat also in chemical composition. Chlorite from Achmatowsk in the Ural is monoclinic; but the variety called *Pennine*, from Zermatt in the Valais, is hexagonal, generally forming six-sided tables with perpendicular edges, oP . ∞ P, or with bevelled edges, oP . P, where P denotes a six-sided pyramid with basal edges of 106° 50′ and pyramidal edges of 132° 40′; also with other faces subordinate. Cleavage perfect, parallel to the base. The crystals are sometimes imbedded singly, but more frequently grouped in spherical, conical, or vermiform masses; also in minute scales, forming a deposit on other minerals. Specific gravity 2·65 to 2·85. Hardness 2·0 to 2·5. Flexible in thin laminæ, but not elastic. Colour various shades of green, from leek to blackish green. Small crystals are dichromatic, appearing red when viewed in a direction perpendicular to the vertical axis. Lustre nacreous on the basal faces, vitreous to waxy on the others. Transparent in thin laminæ, but generally translucent, and transparent on the edges only.

All varieties of chlorite give off water when heated in a tube, and melt with difficulty before the blowpipe to a black slag, sometimes magnetic. The mineral gives with fluxes the reactions of iron, more rarely that of chromium, and is perfectly decomposible by sulphuric acid.

The several varieties of chlorite exhibit considerable diversity of composition; the essential constituents are silica, alumina, magnesia, and water, the alumina, however, being often more or less replaced by ferric oxide and the magnesia by ferrous oxide. The following are analyses: 1. Varrentrapp (Pogg. Ann. xlviii. 185).—2. Kobell

(J. pr. Chem. xvi. 470).—3. **Brüel** (Pogg. Ann. xlviii.)—4. **Delesse** (Ann. Ch. Phys. [3] ix. 396).—5, 6. **Marignac** (*ibid.* x. 430).—7, 8. **Hermann** (J. pr. Chem. xi. 13).—9. **Schweizer** (Pogg. Ann. l. 526).—10, 11. **Marignac** (*loc. cit.*)

	SiO^2	Al^4O^3	Mg^2O	Fe^4O^3	Fe^2O	Mn^2O	H^2O

These numbers may be approximately represented by the formula $2(3M^2O.SiO^2) + Al^4O^3.SiO^2 + 4aq.$ which, if M denotes magnesium, requires 30·82 SiO^2, 17·14 Al^4O^3, 40·03 Mg^2O, and 12·01 water. If alumina be represented as a protoxide (by substitution of $al = \frac{2}{3}$ Al), the preceding formula may be reduced to the form $M^2O.M^4SiO^4 + \frac{2}{3}aq.$ Besides the above localities, chlorite is found on the Col de Pertuis, in the Vosges, and in various parts of the Eastern United States. (Dana, ii. 294; *Rammelsberg's Mineralchemie*, p. 534; Handw. d. Chem. 2^{te} Aufl. ii. [2] 1106.)

Chlorite Earth is earthy chlorite in the older sense of the word, without regard to the distinction between chlorite and ripidolite, because in the earthy state the two minerals can scarcely be distinguished.

Chlorite Ferruginous. *Delessite.*—This mineral occurs in the amygdaloïdal porphyry of Oberstein and Zwickau. It is massive, with short fibrous or scaly feathery texture. Specific gravity 2·89. Hardness 2·5. Colour olive-green to blackish-green. According to Delesse (Ann. Min. [4] xvi. 520) it contains 29·45 per cent. SiO^2, 18·25 Al^4O^3, 8·17 Fe^4O^3, 15·12 Fe^2O, 15·32 Mg^2O, 0·45 Ca^2O, and 12·57 water (= 99·33), which may be approximately represented by the general formula $2(2M^2O.M^4O^3.2SiO^2) + 5aq.$ *Grengesite*, from Grengesberg in Dalecarlia, containing, according to Hisinger, 27·01 SiO^2, 14·31 Al^4O^3, 2·18 Mn^4O^3, 25·63 Fe^2O, 14·31 Mg^2O, and 12·53 water, appears to be related to it. (Dana, ii. 296; *Rammelsberg's Mineralchemie*, 540.)

Chlorite Slate.—This name is applied to chlorite occurring in mountain masses, including, however, those which are made up in like manner of ripidolite.

Chlorite-Spar. See Chloritoïde.

CHLORITES. $MClO^2$. (Millon, Ann. Ch. Pys. [3] vii. 298; Ann. Ch. Pharm. xlvi. 281.)—Salts of chlorous acid. Their general properties are described, together with those of the acid, at page 910. Only a few of them have been studied individually.

Chlorite of Barium. $BaClO^2$.—Obtained by saturating chlorous acid with baryta. By quickly evaporating the solution and finishing the evaporation in vacuo, it may be obtained crystallised and free from chlorite. It dissolves readily in water, and decomposes at 235° C.

Chlorite of Lead, $PbClO^2$, is prepared by adding nitrate of lead to chlorous acid nearly neutralised with lime or baryta, washing the sulphur-yellow scaly precipitate thereby produced, and drying it. If the solution be warmed before adding the nitrate of lead, the chlorite of lead is deposited in larger crystalline scales. The salt decomposes with a kind of explosion at 126° C. (Millon), at 100° (Schiel, Ann. Ch. Pharm. cix. 317). It sets fire to flowers of sulphur when triturated therewith (Millon); when rather large quantities of the salt are mixed with sulphur or a sulphide of an electronegative metal, the mixture takes fire spontaneously after some time (Schiel). Chlorite of lead introduced into sulphydric acid gas blackens at first, but afterwards turns white, from formation of sulphate of lead. With a mixture of equal parts of strong sulphuric acid and water, it evolves pure chlorous anhydride (Cl^2O^3), especially between 40° and 50° C., and yields 88·75 per cent. of sulphate of lead. (Millon.)

The mother-liquor filtered from the precipitate of chlorite of lead in the above-described mode of preparation, deposits on the sides of the vessels, small sparingly soluble yellowish crystals, which appear to be a compound of chlorite and chloride of lead. (Schiel.)

Chlorite of Potassium. $KClO^2$.—Potash-ley, mixed with excess of chlorous acid, forms a deep red liquid, which, when concentrated, gives off chlorous anhydride, and leaves neutral chlorite of potassium in the form of a very deliquescent salt. If, on the contrary, chlorous acid be gradually added to an excess of hydrate of potassium, the formation of the neutral salt takes a longer time, and even after the liquid has become colourless, the presence of free chlorous acid may be detected by its power of converting nitrate of lead into the peroxide. The saline solution must be quickly evaporated, otherwise the chlorite of potassium will be completely resolved into chloride and chlorate. The same decomposition takes place if it be heated to 160° C. (Millon.)

Chlorite of Silver. $AgClO^2$.—Prepared by mixing a soluble chlorite containing a slight excess of base with nitrate of silver, and boiling the resulting precipitate of chlorite and oxide of silver with water. The solution on cooling deposits the salt in yellow crystalline scales. At 105° C. it decomposes with explosion. A mixture of it with sulphur takes fire when triturated with a glass rod. In preparing the salt, an excess of chlorous acid must be avoided, as it would thereby be quickly resolved into chlorate and chloride. (Millon.)

Chlorite of Sodium. $NaClO^2$.—Deliquescent. Resembles the potassium-salt, but is not decomposed by a heat below 250° C. (Millon.)

Chlorite of Strontium. $SrClO^2$.—Deliquescent. Decomposes at 208° C. (Millon.)

CHLORITOÏDE. *Chlorite Spar, Barytophyllite, Masonite.*—A coarsely foliated massive silicate of alumina and iron found at Kosoibrod in the Ural, Bregratten in the Tyrol, and Gummuch-dagh in Asia Minor. Its specific gravity is 3·557; hardness 5·5 to 6; colour dark grey or greenish black; lustre faint and pearly. Gives off water when heated in a tube, is infusible before the blowpipe, but becomes darker and magnetic. It dissolves completely in sulphuric acid.

Allied to chloritoïde are: *Masonite*, from Rhode Island, which fuses with difficulty to a dark green enamel, and *Sismondine*, a dark greyish or blackish green mineral of specific gravity 3·565 and hardness 5·5. Nearly infusible before the blowpipe, occurring in the chlorite slate of St. Marcel.

Analysis: *Chloritoïde.*—1. O. Erdmann (J. pr. Chem. vi. 86).—2. Bonsdorff (Berz. Jahresber. xviii. 233).—3. Hermann (J. pr. Chem. liii. 13).—4. Smith (Ann. Min. [4] xviii. 300).—5. Kobell (J. pr. Chem. lviii. 40. *Masonite*, Whitney, (Proc. Boston Soc. Nat. Hist. 1849, p. 100). *Sismondine*, Delesse (Ann. Ch. Phys. [3] ix. 385).

Chloritoïde	SiO^2	Al^4O^3	Fe^4O^3	Fe^2O	Mn^2O	Mg^2O	Lime and alkali	H^2O
1. Kosoibrod .	24·90	46·20	—	28·89	—	—	—	— = 99·99
2. ,, .	27·48	35·57	—	27·05	0·30	4·29	—	6·95 = 101·64
3. ,, .	24·54	30·72	17·8	17·80	—	3·75	—	6·38 = 99·97
4. Gummuch-dagh	23·75	39·84	—	27·62	0·52	0·58	0·94	6·85 = 100·10
5. Bregratten .	26·19	38·30	6·00	21·11	—	3·30	—	5·50 = 100·40

Among these analyses Nos. 3 and 5 of chloritoïde are the only ones in which the degree of oxidation of the iron appears to have been correctly determined; these agree approximately with the formula $(2M^2O.SiO^2).(M^4O^3.SiO^2) + 2aq.$, which, by substituting proto- for sesqui-equivalent metals, may be reduced to $M^2O.2(M^4SiO^4.aq)$. (*Rammelsberg's Mineralchemie*, p. 864; Dana, ii. 298.)

CHLOROBENZALDIDE. Syn. with Chloride of Benzoyl. (See Benzoyl, Chloride of, p. 566.)

CHLOROBENZAMIDE. See Benzamide (p. 540).

CHLOROBENZENE. See Benzene (p. 543).

CHLOROBENZIDE. Syn. with Trichlorobenzene. (See Benzene, p. 543).

CHLOROBENZIL. $C^{14}H^{11}ClO^2$. (Cahours, Ann. Ch. Phys. [3] xxiii. 350.) —Formed by the action of pentachloride of phosphorus on benzilic acid: the product is distilled, and the portion which comes over above 250° C. washed, dried, and rectified. It is a colourless, strongly-smelling oil, heavier than water; boils at about 270°. By exposure to moist air, or by the action of hot strong potash, it is quickly decomposed into chloride and benzilate. With ammonia and phenylamine, it yields crystalline products. F. T. C.

CHLOROBENZOIC ACID. See Benzoic Acid.

CHLOROBENZOL. Syn. with Chloride of Benzylene. (See Benzylene, Chloride of, p. 577.)

CHLOROBENZONITRILE. See Benzonitrile (p. 563).

CHLOROBENZOPHENIDE. See Benzoic Ethers under Benzoic Acid (p. 554).

CHLOROBENZOYL, CHLORIDE OF. See Benzoyl, Chloride of (p. 56).

CHLOROCAFFEINE. $C^8H^9ClN^4O^2$.—A product obtained by the incomplete action of chlorine on caffeine suspended in water (p. 708). When purified by three or four crystallisations from water, it forms a light bulky mass. From alcohol it crystallises in needles. By the continued action of chlorine, it is resolved into chloride of cyanogen, methylamine, and amalic acid. (Rochleder, Wien Akad. Ber. 1858 ii. 96.)

CHLOROCAMPHENE. See Camphene (p. 724).

CHLOROCARBO-HYPOSULPHURIC ACID. Syn. with Trichloromethylsulphurous Acid. (See Methyl.)

CHLOROCARBONIC ACID. Syn. with Oxychloride of Carbon, Chloride of Carbonyl, or Phosgene (p. 774).

CHLOROCARBONIC ETHERS. Compounds produced by the action of chloride of carbonyl on the alcohols. They may be regarded as compounds of carbonic anhydride with the chlorides of the alcohol-radicles, or as bodies formed on the mixed type HHO.HCl, in which 2 at. of hydrogen are replaced by carbonyl, CO, and the third by an alcohol-radicle, R:

$$CO^2.RCl = \left.\begin{matrix} CO'' \\ R \end{matrix}\right\} \begin{matrix} Cl \\ O \end{matrix}$$

Their formation is represented by the equation:

$$CO''\left\{\begin{matrix} Cl \\ Cl \end{matrix}\right. + \left.\begin{matrix} R \\ H \end{matrix}\right\} O = HCl + \left.\begin{matrix} CO'' \\ R \end{matrix}\right\} \begin{matrix} Cl \\ O \end{matrix}$$

Chlorocarbonate of Methyl. $C^2H^3ClO^2 = \left.\begin{matrix} (CO)'' \\ CH^3 \end{matrix}\right\} \begin{matrix} Cl \\ O \end{matrix}$. (Dumas and Péligot, Ann. Ch. Phys. lviii. 52.)—Obtained by introducing wood-spirit into a large flask filled with phosgene-gas:

$$CH^3.H.O + COCl^2 = HCl + C^2H^3ClO^2.$$

Colourless, very fluid oil, heavier and more volatile than water; has a penetrating odour; burns with a green flame. Gaseous ammonia converts it into carbamate of methyl (urethylane):

$$CO^2.CH^3Cl + NH^3 = \left.\begin{matrix} N.H^2(CO)'' \\ CH^3 \end{matrix}\right\} O + HCl.$$

Chlorocarbonate of Ethyl. $C^3H^5ClO^2$. (Dumas and Péligot, Ann. Ch. Phys. liv. 226.—Cloez, *ibid.* [3] xvii. 303.—Cahours, *ibid.* [3] xix. 346.)—Prepared like the preceding; also by the mutual action of alcohol and perchloroformic ether, or perchlorinated oxalate of methyl:

$$\underset{\substack{\text{Perchloro-}\\\text{formate of}\\\text{ethyl.}}}{C^3Cl^6O^2} + \underset{\text{Alcohol.}}{2C^2H^6O} = \underset{\substack{\text{Chlorocar-}\\\text{bonate of}\\\text{ethyl.}}}{C^3H^5ClO^2} + \underset{\substack{\text{Trichlorace-}\\\text{tate of}\\\text{ethyl.}}}{C^4H^5Cl^3O^2} + 2HCl.$$

$$\underset{\substack{\text{Perchlor-}\\\text{oxalate of}\\\text{methyl.}}}{C^4Cl^6O^4} + \underset{\text{Alcohol.}}{4C^2H^6O} = \underset{\substack{\text{Chlorocar-}\\\text{bonate of}\\\text{ethyl.}}}{2C^3H^5ClO^2} + \underset{\substack{\text{Oxalate of}\\\text{ethyl.}}}{C^6H^{10}O^4} + 4HCl.$$

Colourless liquid, very mobile, having a suffocating odour which irritates the eyes Perfectly neutral to test-paper. Specific gravity 1·139 at 15° C. Vapour-density 3·823. Boils at 94° C. Very inflammable. Burns with a green flame. Decomposed by hot water, not by cold. Ammonia converts it rapidly into chloride of ammonium and carbamate of ethyl.

Chlorocarbonate of Amyl, $C^6H^{11}ClO^2$, appears to be formed by the action of phosgene gas on amylic alcohol, but is immediately decomposed by moisture and converted into carbonate of amyl.

CHLOROCEROTIC ACID. See Cerotic Acid (p. 887).

CHLOROCINNAMIC ACID. See Cinnamic Acid.

CHLOROCINNOSE. Hydride of Tetrachlorocinnamyl. (See Cinnamyl.)

CHLOROCHLORIC ACID. Cl^6O^{13} (?) A compound obtained, according to Millon, (Ann. Ch. Phys. [3] vii. 298) by passing euchlorine (p. 913) through a series of U-tubes cooled by freezing mixtures, the first to 0° C., the others to −18°. Hydrochloric acid then condenses in the first, and chlorochloric acid in the rest, while free chlorine escapes at the end. Chlorochloric acid thus obtained, is a yellowish-red liquid, which boils at 32° C., and is converted into a yellow gas, which decomposes with explosion at 70°. With caustic potash, it yields a mixture of 2 at. chlorate and 1 at. chlorite of potassium, whence its composition is inferred:

$$Cl^6O^{13} + 3K^2O = 4KClO^3 + 2KClO^2.$$

Chlorochloric acid resembles perchloric oxide, ClO^2, in most of its properties, and approaches very nearly to it in composition ($6ClO^2 = Cl^6O^{12}$); indeed it is most probably nothing but perchloric oxide mixed with excess of chlorine (see p. 913.)

CHLOROCODEINE. See Codeine.

CHLOROCOMENIC ACID. See Comenic Acid.

CHLOROCUMENE. See Cumene.

CHLOROCUMINOL. See Cuminol.

CHLOROCYANAMIDE. } See Cyanamide.
CHLOROCYANILIDE. }

CHLORODRACONESIC ACID. Syn. with Chloranisic Acid. (See Anisic Acid.)

CHLORODRACONYL. When chlorine is passed into oil of tarragon, a viscid oily liquid is found, called *chloride of draconyl*, containing 39·9 per cent. C and 3·5 H, answering approximately to the formula $C^{10}H^{10}Cl^2O.Cl^2$; and this, when treated with alcoholic potash, yields another viscid oil, *chlorodraconyl*, containing 42·5 C and 3·4 H; possibly chloride of draconyl minus the elements of water. (Laurent, Rev. scient. x. 6.—Gerh. iii. 355.)

CHLORŒNANTHIC ACID. See Œnanthic Acid.

CHLOROFORM. *Dichlorinated chloride of methyl. Perchloride of formyl.* $CHCl^3$. Soubeiran, Ann. Ch. Phys. [2] xlviii. 131.—Soubeiran and Mialhé, Ann. Ch. Pharm. lxxi. 225.—Liebig, *ibid.* i. 198; Dumas, Ann. Ch. Phys. [2] lvi. 115.—Regnault, *ibid.* lxxi. 577.—Gm. vii. 342.)—Chloroform was discovered in 1831 by Soubeiran, who called it *Ether bichlorique*, and independently in 1832 by Liebig, who regarded it as a chloride of carbon: its true constitution was discovered by Dumas in 1834. Hutman (J. Chim. méd. [3] iv. 476) states, on the authority of Porta's *Magia naturalis* and Scott's *Letters on Demonology and Witchcraft*, that it was known in former times, and used as a means of producing insensibility.

Formation and Preparation.—1. Chloroform is produced, together with monochlorinated chloride of methyl, CH^2Cl^2, when a mixture of chlorine and gaseous chloride of methyl is exposed to the sun's rays. If the two gases be made to pass continuously into a vessel exposed to the sun and connected with a series of cooled receivers, the chloroform, being the least volatile of the products formed, condenses first, and if the current of chlorine be made rather strong, and the receivers not much cooled, the product consists almost wholly of chloroform.

2. By the action of alkalis on chloral:

$$\underset{\text{Chloral.}}{C^2HCl^3O} + KHO = \underset{\text{Chloroform.}}{CHCl^3} + \underset{\text{Formate of potassium.}}{CHKO^2}.$$

Chloral is distilled with excess of aqueous potash, soda or baryta, or with milk of lime, and the oily distillate is repeatedly agitated with water, separated from the water as completely as possible by decantation, and distilled with 6 or 8 times its volume of strong sulphuric acid in a perfectly dry apparatus. (Liebig.)

3. By the action of nascent hydrogen upon tetrachloride of carbon. (Geuther, p. 765.)

4. By boiling trichloracetic acid with aqueous alkalis:

$$C^2HCl^3O^2 + K^2O = CHCl^3 + K^2CO^3.$$

5. By the action of hypochlorites, or of chlorine, in presence of alkalis on various organic substances, viz.: *a.* On methylic, ethylic, and amylic alcohols, perhaps also on all alcohols of the series $C^nH^{2n+2}O$. With common alcohol and hypochlorite of calcium the principal reaction appears to be:

$$C^2H^6O + 5CaClO = CHCl^3 + Ca^2CO^3 + 2CaCl + CaHO + H^2O;$$

but other products are likewise formed, and chlorine is set free.—*b.* On acetic acid and acetates; probably thus:

$$C^2H^4O^2 + 3CaClO = CHCl^3 + Ca^2CO^3 + CaHO + H^2O.$$

c. On acetone.—*d.* On ethylsulphate or ethyltartrate of calcium.—*e.* On oil of turpentine and its isomers, the oils of lemon, bergamot, copaiba, &c.

The most economical method of preparing chloroform, and that which is always adopted on the manufacturing scale, is the distillation of alcohol with chloride of lime. The proportions used are about 6 pts. chloride of lime diffused through 30 pts. water, and 1 pt. alcohol of 33° Beaumé. The addition of slaked lime is also advantageous, as it absorbs the chlorine, which would otherwise be set free, and thereby diminishes the quantity of secondary products. The following mode of preparation on the large scale is given by Kessler (J. Pharm. [3] xiii. 162).

The apparatus consists of a large leaden cylinder, the sides of which are soldered with lead. Through the middle of the upper end passes a vertical rod, provided at the bottom with fans, and at the top with a curved handle, its lower extremity turning on a pivot in the base of the cylinder. By this arrangement, the mixture may be stirred up during the operation, and the heat thereby equally diffused. In the upper end of the cylinder there is also a wider aperture, which can be closed at pleasure, and through which the materials are introduced; through a third aperture is inserted the delivery-tube by which the chloroform vapour is conveyed to the condensing apparatus. Opposite to this tube there passes, through the upper base of the cylinder, a leaden tube, widened above like a funnel, and reaching just below the surface of the liquid. Into this funnel-tube, at some distance below the funnel, is inserted a steam-pipe, serving to convey steam from a boiler to the inside of the funnel-tube; and above the point of insertion of the steam-pipe, the funnel-tube is furnished with a cock, which, when open, allows the steam to pass upwards to the funnel-tube, and when shut directs it into the mixture in the cylinder. This cock serves to regulate the supply of vapour, and thereby regulates the heat. The chloroform vapour passes upwards through a worm-tube, enclosed in a condensing vessel, to a cooled Woulfe's apparatus, the last bottle but one of which is half filled with alcohol, and the last with cotton saturated with alcohol. A close-shutting wooden cask may be used instead of the leaden cylinder. 40 kilogrammes (88·8 lbs.) of the strongest chloride of lime are introduced into the cylinder by means of a four-cornered wooden funnel adapted to its widest aperture, and provided, near its lower extremity, with two horizontal rollers pressing against each other, as in a rolling-mill; these, when turned by their handles, serve to drive the chloride of lime quickly into the cylinder. 4 kilogrammes (8·8 lbs.) of slaked lime are next introduced in the same manner, and then a hectolitre of water (22 gallons) at a temperature of 80° to 90° C., is poured in. The apparatus is now thoroughly luted, and the contents are well mixed by turning the fans. 4 kilogrammes of commercial alcohol are then poured in, together with the residues of former operations. If the distillation of the chloroform does not immediately begin, steam is admitted from the boiler, and stopped as soon as the distillation is fairly set up. If the evolution of vapour becomes too rapid, cold water is poured in through the funnel-tube. When the reaction is complete, steam is again admitted into the cylinder, and the contents, which are now heated to 100°, frequently stirred. After 3 litres (5¼ pints) have been distilled off, the residue contains scarcely any chloroform or alcohol. The contents of the cylinder are discharged by an opening in the bottom, the liquid portion drawn off, and used in the next operation. The alcohol in the last two Woulfe's bottles likewise serves for the following preparations, and the process may be repeated three or four times in a day. 1 kilogramme of chloride of lime yields from 60 to 80 grammes of pure chloroform.

According to Simerling (Arch. Pharm. [2] liii. 23), the largest quantity of chloroform, in proportion to the alcohol used, is obtained from a mixture of 8 pts. chloride of lime, 1 pt. quicklime, 1 pt. alcohol, and 40 pts. water; the rectified chloroform thus produced, amounts to nearly one-third of the alcohol consumed (8 grm. chloroform from 25 grm. alcohol).

The use of acetone for the preparation of chloroform is not advantageous, because the price of it is high, and the product does not exceed one-third of the acetone used. This proportion was obtained by first distilling 30 grm. acetone with 150 grm. chloride of lime mixed with water, and rectifying the watery distillate with 40 grm. chloride of lime. Chloroform obtained from wood-spirit has an empyreumatic odour, and always blackens when agitated with sulphuric acid. The largest product was 6 grm. chloroform from 50 grm. wood-spirit.

For other methods see Ann. Ch. Pharm. xix. 210.—*Gmelin's Handbook*, vii. 344.

Chloroform may be contaminated with alcohol, ether, and empyreumatic oils. According to Soubeiran, pure chloroform sinks in a mixture of equal parts of oil of vitriol and water. According to Kessler, chloroform containing alcohol diminishes in volume on the application of this test. The presence of alcohol causes opalescence when the chloroform is mixed with water, whereas pure chloroform remains clear (Mialhé, J. Chim. méd. [3] iv. 279). Chloroform containing alcohol acquires a green colour when mixed with chromic acid or with sulphuric acid and acid chromate of potassium; pure chloroform produces no green colour (Cottell, J. Pharm. [3] xiii. 359). Chloroform prepared from wood-spirit is much less pure than that obtained from alcohol. The former is specifically lighter than the latter, has a repulsive empyreumatic odour, and produces unpleasant sensations when inhaled. It is contaminated with about 6 per cent. of an empyreumatic oil, containing chlorine, burning with a smoky flame, lighter than water, and boiling between 85° and 133° C. This oil cannot be completely separated by simple rectification, but is nearly, but not quite, destroyed by distillation with sulphuric acid. A similar oil, but in smaller quantity, is likewise obtained in the preparation of chloroform from alcohol; 20 kilogrammes of chloroform from alcohol yielded, when rectified over the water-bath, only 40 grm. of residue consisting of this oil; it is heavier than water, has an odour different from that of the oil obtained from wood-spirit, and its boiling point varies from 68° to 117° C. (Soubeiran and Mialhé). According to Gregory (Proc. Roy. Soc. Edinb. 1850, p. 391), impure chloroform may be recognised by the disagreeable odour which it leaves, after evaporation, on a cloth which has been moistened with it, and by the yellow or brown colour which it imparts to pure oil of vitriol when agitated therewith. Pure chloroform placed upon oil of vitriol produces a contact-surface convex downwards; impure chloroform gives a plane contact-surface. According to **Roussin** (J. Pharm. [3] xxxiv. 206), the purity of chloroform may be tested by means of *dinitrosulphide of iron*, $Fe^6H^2S^5N^4O^4$ (a salt obtained by the action of ferric chloride or sulphate on a mixture of sulphide of ammonium and nitrite of potassium). Pure chloroform shaken up with this salt, remains colourless; but if it contains alcohol, ether, or wood-spirit, it acquires a dark colour. To purify chloroform, **Gregory** agitates it and leaves it in contact with oil of vitriol till the latter is no longer coloured by it, then removes the chloroform, and places it in contact with a small quantity of peroxide of manganese, to free it from sulphurous acid. According to **Abraham** (Pharm. J. Trans. x. 24), chloroform thus purified quickly decomposes, and is afterwards found to contain hydrochloric acid and free chlorine. According to **Christison** (*ibid.* x. 253), chloroform keeps well after being once treated with oil of vitriol; but the continued action of that liquid (especially if contaminated with nitrous acid) exerts a decomposing action upon it.

Properties.—Pure chloroform is a transparent and colourless oil of specific gravity 1·491 at 17° C. (**Regnault**); 1·52523 at 0° (**Pierre**). It boils at 61° (**Regnault**); at 63·5° with the barometer at 772·52 mm. (**Pierre**). In contact with platinum-wire and with the barometer at 27″ 7‴, it boils in a dry vessel at 60·8°, but in contact with water, at 57·3° (**Liebig**). Its vapour-density is 4·199, according to Dumas; 4·230 according to Regnault. By calculation (2 vol.) it is $\frac{12 + 1 + 3 \times 35\cdot5}{2} \times 0\cdot0693 = 4\cdot141$. Chloroform remains liquid and transparent at −16° C. (**Pierre**), but may be solidified by the cold produced by its own evaporation; when it is thrown upon a double filter, the rapid evaporation at the edges causes the remaining portion to solidify in white tufts (**Soubeiran** and **Mialhé**). It has a very pleasant, penetrating odour, a sweet, fiery taste, and its vapour, when inhaled, produces a sweet taste on the palate. The inhalation of a small quantity of the vapour causes excitement similar to that produced by nitrous oxide; but a larger quantity produces insensibility to pain, in fact, a kind of coma: hence it is extensively used in surgical operations.* According to **Robin** (Compt. rend. xxx. 52) and **Augendre** (*ibid.* xxxi. 679), chloroform preserves meat from putrefaction (200 times its weight, according to Augendre).

Chloroform dissolves slightly in water, imparting its sweet taste to the liquid. It mixes in all proportions with alcohol, and is partially precipitated therefrom by water. It dissolves rapidly in ether. It is quite insoluble in sulphuric acid.

It dissolves *phosphorus*, *sulphur*, *iodine*, and *iodoform*, also many *organic bases* and their *salts*. The solubility of several organic bases in chloroform has been determined by **Michael Pettenkofer** (Jahresber. f. Chem. 1858, p. 363) and **A. Schlimpert** (*ibid.* 1859, p. 405), whose statements however differ widely, as the following table will show:

Quantities of Alkaloïds dissolved by 100 *pts. of Chloroform.*

	Pettenkofer.	Schlimpert.		Pettenkofer.	Schlimpert.
Morphine . . .	0·57	1·66	Veratrine . . .	58·49	11 6
acetate . .	—	1·66	Atropine . . .	51·69	33·0
Narcotine . . .	37·17	—	Strychnine . .	20·16	14·1
Quinine . . .	57·47	15·0	nitrate . .	—	6·6
sulphate . .	—	0	Caffeine . . .	—	11·1
hydrochlorate .	—	11·1	Brucine . . .	56·79	14·0
Cinchonine . .	4·31	2·5	Digitaline . . .	—	1·25
sulphate . .	—	3·0	Aconitine . . .	—	22·0
Quinidine (?) . .	—	25·3	Santonine . . .	—	23·0

Decompositions.—1. Chloroform decomposes when exposed to air and light, with formation of chlorine, hydrochloric acid, and other products; but when kept under water, it remains unaltered (**Marson**, Pharm. J. Trans. viii. 69).—2. At a red heat

---

* "For the introduction of this valuable remedy we are indebted to Dr. Simpson; and although ether, benzole, and many other liquids can produce insensibility to pain, chloroform is of all the most powerful as well as the most manageable. Of course great care must be taken to insure its purity, for the oils which accompany it are very deleterious; and in administering it, one person should do nothing but watch the pulse and respiration of the patient and remove the chloroform if necessary. With due precaution, chloroform is very safe; and this precaution will prevent its being used in cases where its use is contra-indicated by the disease of the heart, or by marked tendency to apoplexy." (**Gregory**, *Handbook of Organic Chemistry*, 3rd ed. London, 1852, p. 178.)

its vapour appears to be resolved, partly into trichloride of carbon and hydrogen gas, partly into carbon, hydrochloric acid, and chlorine:

$$2CHCl^3 = C^2Cl^6 + H^2$$

and:

$$CHCl^3 = C + HCl + Cl^2$$

The liberation of chlorine in this manner is applied to the detection of chloroform in blood. A quantity of blood, not less than an ounce, is introduced, immediately after its separation from the organism, into a flask connected by a cork with a knee-shaped tube somewhat drawn out in the horizontal arm. A strip of paper, moistened with starch-paste and iodide of potassium, is inserted into the end of this tube; the drawn-out part is heated to redness; and the flask is heated in a water-bath. The vapour of chloroform thereby evolved is decomposed at the red-hot part of the tube, and the liberated chlorine turns the paper blue. This method is said to be capable of detecting 1 pt. of chloroform in 1,000,000 pts. of blood (Ragsky, J. pr. Chem. xlvi. 170). According to Duroy (J. Pharm. [3] xx. 401), it is not to be depended on unless the blood be taken from the animal immediately after the inhalation of the chloroform, or immediately after death. Duroy considers it better to pass a stream of cold air through the blood; then pass the air, together with the chloroform-vapour, through a red-hot tube, and thence into a solution of nitrate of silver, whereupon, if chloroform be present, a precipitate of chloride of silver will be formed.

3. Chloroform cannot be set on fire in the air, not even with the aid of a wick; but its vapour passed into the flame of a spirit-lamp, burns with smoke; a mixture of chloroform and alcohol in equal measures, burns with a very smoky flame and pungent odour, producing hydrochloric acid (Soubeiran, Liebig). It imparts a green colour to the flame of a candle (Liebig).—4. Chloroform repeatedly distilled in a stream of dry *chlorine*, is resolved into HCl and C^2Cl^4 (Regnault).—5. Chloroform heated with *nitric acid* evolves but a small quantity of nitrous fumes (Soubeiran).—6. When kept under *sulphuric acid*, it gradually gives off vapours of hydrochloric acid. The alcoholic solution of chloroform, mixed with *nitrate of silver*, does not deposit any chloride of silver, even in the course of a month (Soubeiran).—7. Boiled with *potash-ley* in a closed tube, it is resolved into formate and chloride of potassium; but the decomposition is imperfect (Dumas):

$$CHCl^3 + 2K^2O = CHKO^2 + 3KCl.$$

Chloroform is not decomposed by boiling with aqueous alkalis in an open vessel (Liebig). Alcoholic potash boiled for a long time with chloroform, produces formate of potassium (Regnault). A mixture of chloroform, potash, and alcohol, heated in a sealed tube to 100° C. for a week, yields ethylene-gas and formic acid (Berthelot, Ann. Ch. Phys. [3] liv. 87).—8. Chloroform vapour passed over *ignited baryta* or *lime*, yields metallic chloride, carbonate, and charcoal; if the heat be moderate, these products are not accompanied by any gas; but at a full red heat, carbonic oxide is produced by the action of the charcoal on the alkaline carbonate (Liebig, Soubeiran).—9. Chloroform may be distilled over *potassium* without decomposition; but potassium heated in its vapour takes fire with explosion, forming chloride of potassium mixed with charcoal (Liebig). It is not decomposed by *sodium*, even when heated with it to 200° C. in a sealed tube (Heintz). Chloroform is not decomposed by heating with cyanide of potassium, mercury, or silver, even on the addition of alcohol. (Bouchardat.)

A mixture of chloroform and ammonia-gas is decomposed by a heat approaching to dull redness, yielding chloride and cyanide of ammonium:

$$CHCl^3 + 5NH^3 = 3NH^4Cl + NH^4.CN.$$

If the temperature be raised too high, a brown substance is formed, probably paracyanogen. When a solution of ammonia in absolute alcohol is heated with chloroform to a temperature between 180° and 190° C., formate of ammonium may be produced as well as cyanide; in many instances also neither of these salts is formed, but only a brown mass, probably consisting for the most part of paracyanogen. (Heintz, Pogg. Ann. xcviii. 263.)

Chloroform and *phenylamine* do not react at ordinary temperatures; but when equal volumes of the two are heated to 180°—190° C. in a sealed tube, hydrochlorate of phenylamine is formed, together with hydrochlorate of formyl-diphenyl-diamine.

$$CHCl^3 + 4(N.H^2.C^6H^5) = 2[(N.H^2.C^6H^5).HCl] + [N^2.H.(CH)'''(C^6H^5)^2].HCl.$$

(Hofmann, Proc. Roy. Soc. ix. 229.)

CHLOROFORMYL-HYPOSULPHURIC ACID. Syn. with DICHLOROMETHYL-SULPHUROUS ACID. (See METHYL.)

CHLOROGENIC ACID. Syn. with CAFFETANNIC ACID (p. 709).

CHLOROGENIN. A substance which accompanies rubian precipitated from extract of madder by sub-acetate of lead, and forms a green powder when boiled with sulphuric or hydrochloric acid.

CHLOROMELAL. A product of the action of chlorine on hydrate of myricyl (*q. v.*) Its analysis agrees approximately with the empirical formula $C^{30}H^{45\cdot5}Cl^{14\cdot5}O$ (Brodie, Ann. Ch. Pharm. lxxi. 144.)

CHLOROMELANE. See CRONSTEDTITE.

CHLOROMELANILINE. See MELANILINE.

CHLOROMERCURATES. Compounds of mercuric chloride with basic metallic chlorides, or with hydrochlorates of organic bases, *e. g. Chloromercurates of potassium*, KCl.HgCl; KCl.2HgCl; KCl.4HgCl; *Chloromercurate of morphine*, $C^{17}H^{19}NO^3.HCl.4HgCl$. They are obtained by mixing the aqueous or alcoholic solutions of the component salts, and are for the most part crystallisable.

CHLOROMESITATE OF METHYLENE. $C^8H^{10}Cl^2O^2$. — A crystalline substance produced by the action of chlorine on methylic alcohol (*q. v.*)

CHLOROMETHYLASE. $C^2H^2Cl^2$. — An oily liquid produced by the action of potash on acetate of trichloromethyl. It has the composition of *dichlorethylene*, (Laurent, Ann. Ch. Phys. lxiii. 382.) (See ACETATE OF METHYL, p. 23.)

CHLORONAPHTHANE. See NAPHTHALENE.

CHLORONAPHTHALIC ACID. See NAPHTHALENE, CHLORINE-DERIVATIVES OF.

CHLORONICEIC ACID. This name was given by St. Evre (Ann. Ch. Phys. [3] xxv. 484), to an acid crystallising in microscopic four-sided needles, which he obtained by passing chlorine into a solution of benzoate of potassium, containing excess of potash. St. Evre assigned to this acid the formula $C^6H^5ClO^2$. But from the experiments of Pisani, made in Gerhardt's laboratory, it appears that this acid is nothing but chlorobenzoic acid, $C^7H^5ClO^2$. The acid prepared as above was found, after purification by repeated crystallisation, to be identical in composition and properties with chlorobenzoic acid prepared by the action of pentachloride of phosphorus on salicylic acid, or on salycilate of methyl. E. Kopp likewise obtained nothing but chlorobenzoic acid, by passing chlorine into a solution of benzoic acid in caustic soda. Hence also, it may be inferred that St. Evre's *chloroniceamide* is identical with chlorobenzamide; that *chloronicene*, a volatile liquid obtained by distilling chloroniceic acid with baryta or lime, is the same as chlorobenzene, C^6H^5Cl; and that *chloronicine*, a base obtained by the action of sulphide of ammonium on chloronicine, is identical with chlorophenylamine. (Gerh. iii. 980.)

CHLOROPAL. A hydrated ferric silicate, of which there are two varieties, the conchoïdal and the earthy. The former has a pistachio-green colour, is translucent on the edges, has a flat conchoïdal fracture; specific gravity 2·158; hardness 4·5. The latter has a light green colour, verging towards olive-green and brown, is sometimes compact, sometimes friable: the compact variety is very soft. The composition of this mineral varies considerably, as the following analyses will show: 1, 2, from Hungary (Bernhardi and Brandes, Schw. J. xxxv. 29); 3, 4, from the Meenser Steinberg, near Göttingen (Hiller, Jahresber. d. Chem. 1857, p. 671):

	SiO^2	Fe^4O^3	Al^4O^3	Mg^2O	Mn^2O	H^2O	
1. Conchoïdal	46	33	1	2	—	18	= 100
2. Earthy .	45	32	0·75	2	—	20	= 99·75
3. „ .	71·6	16·3	2·1	1·5	trace	8·3	= 99·8
4. Conchoïdal	39·7	28·0	3·7	2·4	trace	26·1	= 99·9

It is perhaps a mixture in variable proportions of opal with a hydrated ferric silicate, $Fe^4O^3.3SiO^2 + 3H^2O$, or $fe^2SiO^3 + H^2O$, or $(fe^2H^2)SiO^4$, the conchoïdal variety analysed by Hiller, containing about 41 per cent. of the ferric silicate, the earthy variety, 70 per cent. (Jahresber. *loc. cit.*)

CHLOROPALLADATES. Compounds of dichloride of palladium with the more basic metallic chlorides, or with hydrochlorates. They are not much known.

CHLOROPALLADITES. Compounds of protochloride of palladium with the more basic metallic chlorides, or with hydrochlorates of organic bases; *e. g.* chloropalladite of potassium, KCl.PdCl; chloropalladite of strychnine, $C^{21}H^{22}N^2O^2.HCl.PdCl$.

CHLOROPALMITIC ACID. See PALMITIC ACID.

CHLOROPERCHLORIC ACID. Cl^6O^{17}?— A compound said to be produced by exposing chlorous anhydride to sunshine, the containing vessel being at the same time immersed in water of 20° C. It is a reddish brown liquid which is decomposed by heat, but not explosively; forms extremely dense white fumes in contact with moist air, and is decomposed by potash; yields 1 at. chlorite and 2 at. chlorate of potassium: $Cl^6O^{17} + 3K^2O = 2KClO^2 + 4KClO^4$. (Millon, Ann. Ch. Phys. [3] vii. 298. It is perhaps hyperchloric oxide, $Cl^6O^{18} = 3Cl^2O^6$ (p. 907).

CHLOROPHÆITE. A ferrous silicate, occurring in foliated or granular massive forms, in the Faroe Islands, also in the neighbourhood of Fife and of Newcastle. It has a dark green colour, and subresinous lustre; specific gravity 2·02; hardness 1·5 to 2. According to Forchhammer's analysis (Berz. Jahresber. xxiii. 265), it contains 32·85 per cent. silica, 21·56 protoxide of iron, 3·44 magnesia, and 12·15 water, whence the formula $2(\frac{7}{9}Fe^2O.\frac{2}{9}Mg^2O).3SiO^2 + 12H^2O$, which may be represented as an orthosilicate of the form $(M^4H^8)Si^3O^{12} + 8H^2O$.

CHLOROPHÆNERITE. A hydrated ferrous silicate, found in cavities of the amygdaloïdal porphyry of Weissig in Saxony. It is blackish-green, with dirty apple-green streak; not very hard; of specific gravity 2·684. Analysis gave 59·4 per cent. SiO^2, 12·3 Fe^2O, and 5·7 H^2O, besides alumina, magnesia, lime, potash, and soda. (Jenzsch, Chem. Centr. 1856, 76.)

CHLOROPHANE. A variety of fluorspar, which emits a green light on calcination.

CHLOROPHENESIC ACID. Syn. with Dichlorophenic acid, $C^6H^4Cl^2O$. (See Phenic Acid.)

CHLOROPHENISIC ACID. Syn. with Trichlorophenic Acid.

CHLOROPHENUSIC ACID. Syn. with Pentachlorophenic Acid.

CHLOROPHENYL. This name was applied by Laurent to a crystalline substance obtained by the action of boiling nitric acid on trichlorophenic acid. It crystallised in yellow scales insoluble in water, soluble in alcohol and ether, and subliming in very brilliant scales. Analysis gave 37·8 per cent. C, 1·88 H, and 54·30 Cl. (Gerh. ii. 28.)

CHLOROPHOSPHIDE OF NITROGEN. See Nitrogen.

CHLOROPHYLL. (Berzelius, Ann. Ch. Pharm. xxi. 257, 262; xxvii. 296.—Verdeil, Compt. rend. xxiii. 689.—Schulze, *ibid.* xxxiv. 683.—Mulder, Ann. Ch. Pharm. lii. 421.)—The colouring matter of leaves and the other green parts of plants. It is extracted by digesting green leaves for several days with ether, evaporating the filtered liquid to dryness, treating the residue with boiling alcohol, and adding to the solution a small quantity of milk of lime, which precipitates all the colouring matter, while the alcohol retains a quantity of fat which was mixed with it. The chlorophyll is separated from the lime by means of hydrochloric acid and ether, which dissolves the colouring matter, forming a green stratum at the top of the liquid. By evaporating the ether, the chlorophyll is obtained in the pure state.

Chlorophyll thus prepared is an earthy powder, of a deep green colour, unalterable in the air, infusible, sustaining a heat of 200° C. without decomposition, but decomposing at higher temperatures. It is insoluble in water, even at the boiling heat; easily soluble in alcohol, less in ether. Acids and alkalis dissolve it with green colour: a solution of alum precipitates it. Nascent hydrogen decolorises it like indigo (Mulder). Mulder represents chlorophyll by the formula $C^9H^9NO^4$, which however cannot be considered as established. According to Verdeil, chlorophyll has a great analogy to the colouring matter of blood, and like that substance, contains a large quantity of iron. According to Morot (Jahresber. f. Chem. 1859, p. 562), chlorophyll is $C^{18}H^{20}N^2O^3$, and is always accompanied by a fatty substance, $C^8H^{14}O$. The latter is produced by the action of atmospheric oxygen on starch, according to the equation;

$$2C^6H^{10}O^5 + O^2 = C^8H^{14}O + 4CO^2 + 3H^2O.$$

and chlorophyll results from the simultaneous action of carbonic acid and ammonia on this fat, under the influence of light:

$$C^8H^{14}O + 2NH^3 + 10CO^2 = C^{18}H^{20}N^2O^3 + O^{18}.$$

According to Schultze, chlorophyll forms the colouring matter of several green animalcules inhabiting ponds and ditches, such as polypes, turbellarias, and infusoria (*Hydra viridis*, *Vortex viridis*, *Mesostomum viridatum*, *Derostomum cæcum*, *Stentor polymorphus*, *Ophrydium versatile*, *Bursaria vernalis*).

The name *Erythrophyll* has been given to the red colouring matter of leaves in autumn. It is soluble in water and alcohol; dissolves with brown colour in alkalis, and forms with lead-salts, a precipitate of a fine green colour.

CHLOROPHYLLITE. An altered form of cordierite, found at Haddam in Connecticut, and Unity, New Hampshire. It occurs in trimetric crystals of the same form as the original cordierite, of greyish or brownish-green colour, and pearly lustre; specific gravity 2·782. According to Rammelsberg's analysis, it contains 46·31 per cent. SiO^2, 25·17 Al^4O^3, 10·99 Fe^4O^3, 10·91 Mg^2O, trace of Mn^2O, 0·58 Ca^2O, and 6·70 water (= 100·66), which numbers, if a small quantity of the iron be supposed to exist as protoxide, may be nearly represented by the formula $2(M^2O.M^4O^3.2SiO^2) + 3aq.$, or

$2(M^2m^6)Si^2O^8 + 3aq.$, which is that of a hydrated cordierite. (*Rammelsberg's Mineralchemie*, p. 833.)

CHLOROPICRIN. CCl^3NO^2. (Stenhouse, Phil. Mag. [3] xxxiii. 53.—Gerhardt and Cahours, Compt. chim. 1849, pp. 34 and 170.)—This compound may be regarded as marsh-gas, CH^4, in which 1 at. H is replaced by NO^2, and 3 more by chlorine. It is produced: 1. By the distillation of picric acid, styphnic acid, or chrysammic acid with chloride of lime and water: hence also when the bodies which yield either of these three acids by treatment with nitric acid are first boiled with nitric acid and then distilled with chloride of lime. To these belong: creosote, salicin, indigo, cumarin, the yellow resin of Botany Bey, liquid storax, benzoin, Peru-balsam, galbanum, gum assafœtida, ammoniacum, purree, aloes, extract of Campeachy wood, log-wood, fustic, red sandal-wood, &c. Lastly, Dammara resin, and the chlorinated resin formed in the decomposition of usnic acid by chlorine, likewise yield chloropicrin, when treated with nitric acid and chloride of lime.—2. By treating picric acid with chlorine water or aqua-regia, or a mixture of chlorate of potassium and hydrochloric acid.

To prepare it, aqueous picric acid is distilled with chloride of lime till, after about a quarter of an hour's boiling, no more heavy oil passes over with the water. Should the residue be still yellow, it must be redistilled with fresh chloride of lime. The oil is separated from the watery distillate, washed with water to which a little carbonate of magnesium has been added, dried by placing it over chloride of calcium, and rectified.

Chloropicrin is a transparent, colourless, strongly refracting oil, of specific gravity 1·6657, boiling at 120° C. Its odour, in the dilute state, is peculiarly aromatic, but in the concentrated state very sharp, and attacks the nose and eyes less persistently, but quite as violently, as volatile chloride of cyanogen and oil of mustard. It is neutral to vegetable colours. It dissolves sparingly in water, very easily in alcohol and ether.

Chloropicrin sustains without alteration a heat of 150° C.; but when passed through a red-hot tube, it is completely decomposed, yielding nitric oxide, chlorine, and trichloride of carbon. A small piece of potassium gently heated in the oil, causes strong explosion: at ordinary temperatures, it forms in a few days chloride and nitrate of potassium. Chloropicrin is not decomposed by aqueous potash, even after prolonged contact; but alcoholic potash gradually decomposes it, forming chloride and nitrate of potassium. Aqueous ammonia exerts scarcely any action upon chloropicrin; but with ammoniacal gas or alcoholic ammonia, it forms chloride and nitrate of ammonium. It is not acted upon by sulphuric, nitric, or hydrochloric acid, even at the boiling heat.

BROMOPICRIN. CBr^3NO^2. (Stenhouse, Phil. Mag. [4] viii. 36.)—Obtained, like chloropicrin, by distilling picric acid with solution of hypobromite of calcium (lime-water containing bromine), and purified by washing with carbonate of sodium, agitation with mercury, and digestion (not distillation) with chloride of calcium. It is a colourless liquid, heavier than water, having the acrid odour of chloropicrin. It is insoluble in water, easily soluble in alcohol and ether. It may be heated to its boiling point (above 100° C.) without decomposition, but is then decomposed, with evolution of brown-red vapours, even in an atmosphere of carbonic anhydride. At a higher temperature, it decomposes with slight explosion. The alcoholic solution is slowly precipitated by nitrate of silver in the cold, immediately when heated.

CHLOROPLATINATES. Compounds of dichloride of platinum with the more basic metallic chlorides, or with the hydrochlorates of organic bases: *e.g. Chloroplatinate of ammonium*, $NH^4Cl.PtCl^2$; *Chloroplatinate of Strychnine*, $C^{21}H^{22}N^2O^2.HCl.PtCl^2$. (See PLATINUM.)

CHLOROPLATINITES. Compounds of protochloride of platinum with more basic metallic chlorides: *Chloroplatinite of potassium*, KCl.PtCl. (See PLATINUM.)

CHLORORHODATES. Compounds of sesquichloride of rhodium with more basic chlorides, *e. g. Chlororhodate of ammonium*, $2NH^4Cl.R^2Cl^3$.

CHLORORUBIN. See RUBIAN and MADDER.

CHLOROSALICIN. See SALICIN.

CHLOROSALIGENIN. See SALIGENIN.

CHLOROSAMIDE. Syn. with HYDRIDE OF CHLORAZOSALICYL. (See SALICYL.)

CHLOROSPINEL. A grass-green spinel from Slatoust in the Ural, of specific gravity 3·591—3·594. It contains, according to two analyses by H. Rose (Pogg. Ann. i. 620):

Al^4O^3	Fe^4O^3	Mg^2O	Cu^2O	Ca^2O	
64·13	8·70	26·77	0·27	0·27	= 100·24
57·34	14·77	27·49	0·62	—	= 100·22

whence the formula $Mg^2O.(Al^4O^3 ; Fe^4O^3)$ or $Mg(Al ; Fe)^2O^2$. It is distinguished from Ceylonite (p. 843) by the absence of ferrous oxide.

CHLOROSTRYCHNINE. See Strychnine.

CHLOROSTYRACIN. See Styracin.

CHLOROSUCCIC ACID. An acid obtained by the metamorphosis of perchlorinated succinate of ethyl. (See Succinic Ethers.)

CHLOROSUCCINIMIDE. See Succinimide.

CHLOROTEREBENE. See Terebene.

CHLOROSULPHURIC ACID. See Sulphuryl, Chloride of.

CHLOROVALERISIC ACID. Syn. with Trichlorovaleric Acid. (See Valeric Acid.)

CHLOROVALEROSIC ACID. Syn. with Tetrachlorovaleric Acid.

CHLOROXALOVINIC ACID. See Oxalic Ethers.

CHLOROXAMETHANE. Syn. with Pentachlorinated Oxamate of Ethyl. (See Oxamic Ethers.)

CHLOROXETHIDE. Syn. with Chloroxalovinic Anhydride. (See Oxalic Ethers.)

CHLOROXETHOSE. C^4Cl^6O. (Malaguti, Ann. Ch. Phys. [3] xvi. 19.—Obtained by the action of monosulphide of potassium on perchloric ether:

$$C^4Cl^{10}O + 2K^2S = 4KCl + S^2 + C^4Cl^6O.$$

To prepare it, 50 pts. of monosulphide of potassium are heated with 16 pts. of perchloric ether and 200 pts. of alcohol of 95 per cent. Chloride of potassium is then deposited; the liquid assumes a dark colour; and after a day, the deposit of chloride of potassium becomes covered with crystals of sulphur. On adding water to the liquid, chloroxethose separates in the form of an oil.

It is a colourless, limpid, oily liquid, having an agreeable odour like that of meadow-sweet, and a saccharine taste. Specific gravity 1·654 at 20° C. Boils at 210° C. with slight decomposition. Insoluble in water, soluble in alcohol and ether. It is altered after some time by exposure to the air. It is not attacked by alkalis or by ordinary nitric acid; but nitric acid of specific gravity 1·5 attacks it strongly when heated. On exposing it to sunshine in an atmosphere of chlorine, crystals of perchloric ether make their appearance after a few days: $C^4Cl^6O + Cl^4 = C^4Cl^{10}O$. It likewise absorbs bromine in sunshine, producing perchlorobromic ether. Exposed to the action of chlorine under a layer of water, it yields hydrochloric and trichloracetic acids:

$$C^4Cl^6O + Cl^4 + 3H^2O = 4HCl + 2C^2HCl^3O^2.$$

CHLOROXYNAPHTHALIC ACID. See Oxynaphthalic Acid.

CHOCHOCA. A name applied by the natives of South America to dried potatoes prepared by exposing the peeled and boiled tubers to the alternate action of frost and sunshine.

CHODNEFFITE. Syn. with Cryolite.

CHOLACROL. $C^8H^{10}N^4O^{13} = C^8H^{10}(NO^2)^4O^5$ (?)—A product of the action of nitric acid upon bile. This action gives rise to both fixed and volatile products. The volatile substances formed are capric, caprylic, valeric, and butyric acid, together with an oily body which, when treated with strong caustic potash, is resolved into nitrocholic acid and cholacrol, which latter may be separated from the saline solution by decantation. It is an oily neutral body having a strong odour; dissolves sparingly in water, freely in alcohol and ether; when heated, it decomposes with slight explosion. (Redtenbacher, Ann. Ch. Pharm. lvii. 145.)

CHOLALIC ACID. $C^{24}H^{40}O^5$.—Syn. with cholic acid, the non-azotised acid obtained by the action of alkalis on taurocholic and glycocholic acids. (See Cholic Acid.)

CHOLEIC ACID. Syn. with Taurocholic Acid, the sulphuretted acid of bile.

CHOLESTERIC ACID. $C^8H^{10}O^5$.—This acid is produced, together with choloïdanic acid, oxalic acid, several volatile acids, and a resinous substance, by the action of nitric acid on cholesterin. Choloïdic and glycocholic acids treated with nitric acid yield the same products. To prepare it, cholesterin is treated with nitric acid in a retort, the distilled liquid being frequently poured back, whereby a resinous mass is produced, which slowly dissolves after prolonged boiling with excess of nitric acid. The liquid, when sufficiently concentrated in the retort, leaves an acid gummy residue, containing a large quantity of cholesteric acid, mixed with choloïdanic acid and a resinous substance; and this residue, on cooling, separates into two layers, the upper of which consists of crystalline choloïdanic acid, while the lower, which is viscid, consists chiefly of cholesteric acid containing a little oxalic acid. On saturating this liquid with ammonia, precipitating by nitrate of silver, and boiling the precipitate with water, cholesterate of silver is deposited in crystalline crusts, which, when decomposed by sulphuretted hydrogen, yield the acid.

Cholesteric acid is a yellowish gummy solid, resembling the gum of the cherry-tree. It is deliquescent; very soluble in water and alcohol; has an acid, bitter, and astringent taste, and is decomposed by distillation, giving off bitter vapours and leaving a considerable quantity of charcoal.

The formula of the *cholesterates* is $C^8H^8M^2O^5$. The alkaline and earthy salts are soluble and uncrystallisable; the cholesterates of the heavy metals are insoluble.

CHOLESTERIN. $C^{26}H^{44}O$.—This substance was first obtained by Conradi, in 1775, from human gall-stones, of which it sometimes constitutes nearly the entire substance. It has been found in human bile by Chevreul (Ann. Chim. xcv. 5; xcvi. 166); in the blood by Lecanu (Ann. Ch. Phys. lxvii. 54), Boudet (*ibid.* lii. 336), Denis (J. Chim. méd. [2] iv. 161), and by Becquerel and Bodier (Gaz. méd. No. xlvii.); in the brain (Couerbe, Ann. Ch. Phys. lvi. 281; Frémy, *ibid.* [3] ii. 486), in yolk of egg (Lecanu, J. Pharm. xv. 1; Gobley, *ibid.* [3] xii. 12), and in certain morbid products of the animal economy, such as cerebral concretions, scirrhous matter of the mesocolon, hydropic liquid of the abdomen, ovaries, testicles, &c. (Lassaigne Ann. Ch. Phys. ix. 324; O. Henry, J. Chim. méd. i. 280; Caventou, J. Pharm. xi. 462; Lehmann, Lehrb. d. Physiol. Chem. 2te Aufl. i. 286). The first exact analysis of cholesterin was made by Chevreul, who assigned to it the formula above given. Its metamorphoses have been studied by Marchand (J. pr. Chem. xvi. 37), Redtenbacher (Ann. Ch. Pharm. lvii. 145), Meissner and Schwendler (*ibid.* lix. 107; and J. pr. Chem. xxxix. 247), Zwenger (Ann .Ch. Pharm. lxvi. 5; lxix. 347), Heintz (Pogg. Ann. lxxix. 524), and Berthelot (Ann. Ch. Phys. [3] lvi. 51).

Cholesterin is easily prepared by crystallising *biliary calculi* from boiling alcohol, to which a little potash is added to dissolve any fatty acids that may be present. The cholesterin is then deposited in colourless nacreous laminæ. To obtain cholesterin from brain, that substance is treated with ether, the ethereal extract boiled with alcoholic potash, and the liquid left to cool. It then deposits cholesterin mixed with cerebrate and phosphate of potassium, from which the cholesterin may be dissolved out by ether.

Cholesterin is white, tasteless, inodorous, insoluble in water, sparingly soluble in cold alcohol, but dissolves very easily in boiling alcohol, from which it separates on cooling in beautiful crystalline nacreous laminæ, soft to the touch, and melting at 137° C. It dissolves also in ether, wood-spirit, oil of turpentine, soap-water, and neutral fats. A solution of cholesterin in a mixture of 2 vols. alcohol and 1 vol. ether deposits by spontaneous evaporation laminated transparent crystals of hydrate of cholesterin, $C^{26}H^{44}O + H^2O$, which give off their water at 100° C.

Cholesterin resists the action of concentrated alkaline solutions even at the boiling heat; but lime decomposes it at about 250° C., hydrogen being given off and the cholesterin being converted into an amorphous fatty body nearly insoluble in alcohol.

Cholesterin is attacked by *chlorine* and *bromine*, yielding substitution-products; the *chlorine* compound is $C^{26}H^{36}Cl^8O$. For the action of nitric acid upon cholesterin, see CHOLESTERIC ACID.

Cholesterin sublimes without alteration at 200° C., but decomposes at a higher temperature, yielding several oily products and a solid body. When distilled in a retort, it yields a carbonaceous residue and a neutral oily liquid insoluble in potash, from which a second distillation with water separates a volatile oil having the agreeable odour of geraniums.

When *strong sulphuric acid* is gradually added to a slightly heated mixture of cholesterin and dilute sulphuric acid, the cholesterin becomes soft, acquires a deep red colour, and decomposes, giving off all its oxygen in the form of water, and is changed, without evolution of gas, into three isomeric hydrocarbons, which Zwenger designates as cholesterilin, *a*, *b*, and *c*; they are insoluble in water, and may be freed from sulphuric acid by washing with that liquid. These hydrocarbons are easily crystallisable, and like cholesterin are remarkable for possessing high melting points. *a* has an earthy aspect, melts at 240° C., and is nearly insoluble in alcohol, very sparingly soluble in ether; *b* forms shining scales melting at 255°, moderately soluble in hot ether; if kept in the fused state it loses the power of crystallising; *c* is resinous without appearance of crystallisation, and melts at 127°, it is also soluble in hot ether.

With concentrated *phosphoric acid*, cholesterin forms two compounds, called cholesterone, *α* and *β*, isomeric with each other, but differing in physical properties. Cholesterone *α* forms very brilliant rectangular prisms, melting at 68° C., and distilling almost without alteration; easily soluble in alcohol and ether. The modification *β* forms small silky needles sparingly soluble in ether, nearly insoluble in alcohol.

The composition of cholesterilin and cholesterone agrees nearly with the formula

$C^{26}H^{42}$; they are, therefore, either isomeric or polymeric. Their formation from cholesterin is represented by the equation:

$$C^{26}H^{44}O - H^2O = C^{26}H^{42}.$$

This decomposition shows that cholesterin partakes of the nature of an alcohol; it is, in fact, homologous with cinnamic alcohol, and its formula may be written $C^{26}H^{43}.H.O$. Heated with acetic, butyric, benzoic, and stearic acids, it forms compound ethers, with elimination of water; thus with stearic acid:

$$\underset{\text{Stearic acid.}}{\left.\begin{matrix}C^{18}H^{35}O\\H\end{matrix}\right\}O} + \underset{\text{Cholesterin.}}{\left.\begin{matrix}C^{26}H^{43}\\H\end{matrix}\right\}O} = \underset{\text{Stearate of cholesteryl.}}{\left.\begin{matrix}C^{18}H^{35}O\\C^{26}H^{43}\end{matrix}\right\}O} + H^2O.$$

These ethers are prepared in the same manner as the glycerides, and are purified by boiling the product with eight or ten times its volume of alcohol, which extracts the unaltered cholesterin, and crystallising from boiling ether.

Benzoate of Cholesteryl, $C^{33}H^{48}O^2 = C^7H^5O.C^{26}H^{43}.O$, crystallises in small shining micaceous laminæ, which melt between 125° and 130° C., dissolve with moderate facility in ether, very sparingly in boiling alcohol. The *butyrate*, $C^4H^7O.C^{26}H^{43}.O$, is easily fusible, somewhat soluble in hot alcohol. The *stearate*, $C^{18}H^{35}O.C^{26}H^{43}.O$, crystallises in small shining needles, having a neutral reaction, sparingly soluble in cold ether, nearly insoluble in alcohol even at the boiling heat. The *acetate* has likewise been formed, but is difficult to purify, being more soluble in alcohol than the preceding compounds. (Berthelot.)

CHOLESTROPHANE. $C^5H^6N^2O^3$.—The name given by Rochleder to the final product of the action of chlorine on caffeine (*q. v.*), called also *nitrotheine* by Stenhouse, and regarded by Gerhardt as *dimethylparabanic acid*, $C^3(CH^3)^2N^2O^3$. It is also obtained by the action of nitric acid upon caffeine. It is soluble in alcohol, and crystallises in iridescent scales, which sublime at 100° C. Boiled with potash it yields carbonate and oxalate of potassium, and gives off ammonia (according to Rochleder), or rather methylamine.

CHOLIC ACID. *Cholalic Acid.** $C^{24}H^{40}O^5$.—This acid was discovered by Demarçay in 1838 (Ann. Ch. Phys. [2] lxvii. 177), further examined by Theyer and Schlosser (Ann. Ch. Pharm. xlviii. 77; l. 235), and finally by Strecker (*ibid.* lxv. 9; lxvii. 1; lxx. 161, 166). It is produced by the action of alkalis on the acids of bile, viz. glycocholic and taurocholic acids, the decomposition taking place in the manner represented by the equations:

$$\underset{\text{Glycocholic acid.}}{C^{26}H^{43}NO^6} + H^2O = \underset{\text{Cholic acid.}}{C^{24}H^{40}O^5} + \underset{\text{Glycocine.}}{C^2H^5NO^2}.$$

$$\underset{\text{Taurochloric acid.}}{C^{26}H^{45}NSO^7} + H^2O = \underset{\text{Cholic acid.}}{C^{24}H^{40}O^5} + \underset{\text{Taurine.}}{C^2H^7NSO^3}.$$

Cholic acid does not exist ready formed in normal bile, but is produced from the nitrogenised acids of bile during the putrefaction of that liquid after its removal from the body. Similar changes appear also to take place within the body in certain states of disease; hence, according to Thudichum, it occurs in gall-stones (p. 588).

The easiest mode of preparing cholic acid is to boil the resinous acids precipitated by ether from an alcoholic solution of bile (p. 585) with baryta-water in a retort having its neck directed upwards, adding as much hydrate of barium as will dissolve in the boiling liquid, and continuing the ebullition for about twelve hours. The crystalline mass of hydrate and cholate of barium obtained on cooling, is decomposed by hydrochloric acid, the cholic acid then separating as a glutinous resin, while chloride of barium remains in solution. The cholic acid is suffered to remain in the liquid till it is completely solidified, a few drops of ether being added to accelerate the process, after which it is washed with cold water, dissolved in boiling alcohol or ether, and the solution left to crystallise. Potash may be used in the preparation instead of baryta, but it is less advantageous.

Cholic acid has a bitter taste, with slight saccharine aftertaste. It crystallises in two different forms, and with different quantities of crystallisation-water, according as it is deposited from alcohol or ether.

a. $2C^{24}H^{40}O^5.5H^2O$. This hydrate is deposited from boiling alcohol. It forms tetrahedral or more rarely octahedral crystals, belonging to the dimetric system. Observed combinations $\frac{P}{2} . \infty P$ and $P . \infty P\infty$. Ratio of principal to secondary axis

---

* Cholic acid is the name originally proposed by Demarçay. Strecker afterwards altered it to cholalic acid, reserving the term cholic acid for the nitrogenous bile-acid which yields this acid, together with glycocine, by decomposition; but it is more systematic to call this nitrogenised acid glycocholic acid, and retain Demarçay's name for the non-azotised acid.

= 0·7946; P : P, in the terminal edges = 116° 114′; in the lateral edges = 96° 40′. The crystals are colourless, very brittle, and have a glassy lustre. In a dry atmosphere they lose their water of crystallisation, and become opaque. They dissolve in 750 pts. of boiling water, in 4000 pts. of cold water, in 20·8 pts. of cold alcohol of 70 per cent., and are very soluble in boiling alcohol. The alcoholic solution becomes milky on addition of water, and after a while deposits shining needles. 1 pt. of cholic acid (? the $\frac{5}{2}$-hydrate), dissolves in 27 pts. of ether.

b. $C^{24}H^{40}O^5.H^2O$. This hydrate is deposited from boiling ether, in crystals belonging to the trimetric system, exhibiting the combination ∞P . ∞P̆∞ . P, but having the aspect of monoclinic crystals, in consequence of the predominance of one half of the P-faces in the same zone. Ratio of brachydiagonal, macrodiagonal, and principal axis = 0·6036 : 1 : 0·3752. Inclination of faces, P : P = 71° 58′; 119° 36′, and 144° 39′; P : ∞P = 125° 39′; ∞P : ∞P = 62° 15′; ∞P̆∞; ∞P = 148° 53′. (H. Kopp.)

The two hydrates above described seem to contain different modifications of cholic acid; the dimetric variety gives off all its water at 100° C., and may then be heated to 170° without decomposing, whereas the trimetric modification is not easily dehydrated at 100°, and melts, with decomposition, at 150°. The two modifications, however, yield the same salts, and are easily converted one into the other.

Cholic acid heated to 200° C. gives off the elements of 1 at. water, and is converted into choloïdic acid: $C^{24}H^{40}O^5 - H^2O = C^{24}H^{38}O^4$, and at 290° it is converted in like manner into dyslysin: $C^{24}H^{40}O^5 - 2H^2O = C^{24}H^{36}O^3$. By distillation, it yields a yellowish, very acid oil, with only a very slight carbonaceous residue. The oil is soluble in ether and in alkalis: the alkaline solution precipitates metallic salts.

Cholic acid dissolves easily in caustic alkalis, also in hot solutions of alkaline carbonates, expelling the carbonic acid. The CHOLATES, $C^{24}H^{39}MO^5$, have a very bitter taste. sometimes slightly saccharine; they are soluble in alcohol; those of the earth-metals and heavy metals are sparingly soluble in water, and may be obtained by precipitation.

Cholic acid and its salts give with sulphuric acid and sugar the reaction already described as Pettenkofer's test for bile (p. 586).

Cholate of Ammonium, obtained by passing ammonia-gas into an alcoholic solution of cholic acid and precipitating by ether, forms slender needles, soluble in water. It is decomposed by prolonged exposure to the air, with loss of ammonia, more quickly when boiled with water.

Cholate of Barium, $C^{24}H^{39}BaO^5$, is obtained by dissolving the acid in baryta-water, precipitating the excess of baryta by carbonic acid, and concentrating the filtrate, as a crystalline pellicle mammellated on the surface, silky in the interior. It dissolves in 30 pts. of cold, 23 pts. boiling water, and in a smaller quantity of alcohol. The solutions are decomposed by a continued stream of carbonic acid. A concentrated solution of cholate of potassium yields a white flaky precipitate with chloride of barium.

Cholate of Calcium, is precipitated in thick clots, which crystallise from ether. The *copper-salt* is a bluish-white precipitate. The *lead-salt* is white, sparingly soluble in water, soluble in alcohol and acetic acid. The *manganese-salt* is a semi-crystalline flocculent precipitate. The *mercury-salts* are white precipitates, which dissolve slowly by ebullition.

Cholate of Potassium, precipitated by ether from its alcoholic solution, or obtained by spontaneous evaporation, forms slender needles. From its aqueous solution it is precipitated by strong potash. *Cholate of sodium* resembles the potassium-salt.

Cholate of Silver is obtained as a white precipitate, which partly dissolves on boiling, and crystallises as the solution cools. It blackens slightly at 100° C., dissolves easily in alcohol.

CHOLOCHROME. The general name for the colouring matters of bile; it includes the ordinary brown bile-pigment called cholophæin or biliphæin; a green substance, cholochloin or biliverdin, produced by oxidation of cholophæin; and cholofulvin or bilifulvin, a yellow substance found in thickened ox-bile. These substances were first examined by Berzelius (Lehrb. d. Chem. ix. 281), afterwards by Simon, Plattner, Schmid, Scherer and Heintz (Gerh. *Traité*, iv. 532), and Thudichum (*British Medical Journal*, July 14th, 1860).

Cholophæin, or the brown pigment, is contained in bile and in the intestinal canal, and is the substance to which excrements owe their colour. In certain states of disease it occurs in the blood, the serous fluids, the urine, and other liquids of the organism, and is the cause of the yellow colour of the skin and the cornea in jaundice. It is most conveniently prepared from gall-stones, of which it sometimes forms the chief part, by exhausting them with alcohol, ether, and boiling water; washing the residue with hydrochloric acid, then with water; dissolving it in a weak solution of carbonate of sodium; and precipitating by an acid. As the cholophæin is very apt to pass into the green pigment by oxidation, it is best to perform all these operations in an atmosphere of hydrogen (Heintz). From human gall-stones cholophæin may also be extracted by benzene or by chloroform. (Thudichum.)

Cholophæin recently precipitated is a brown amorphous substance, becoming darker when dry. It is infusible, insoluble in boiling water; soluble in boiling alcohol, the solution gradually turning green by contact with the air. Hydrochloric acid dissolves it in small quantity, acquiring a blue colour. On adding excess of ammonia, the liquid immediately acquires a greenish-yellow colour, which is changed to red by nitric acid.

Cholophæin contains, according to Heintz's analysis, 60·9 per cent. carbon, 6·05 hydrogen, and 9·1 oxygen, whence may be deduced the empirical formula, $C^{16}H^{18}N^2O^{4\cdot5}$ (61·9 C, 58 H, 9·0 N, and 23·2 O).

Caustic alkalis and alkaline carbonates dissolve cholophæin with brownish-yellow colour: the ammoniacal solution yields a brown flaky precipitate with chloride of barium or chloride of calcium. A solution of cholophæin in very dilute alcoholic potash assumes a green colour on addition of hydrochloric acid; and if nitric acid be then added drop by drop, a fine blue colour is produced, which lasts a long time.

Cholochloïn or *Biliverdin.*—This green pigment is produced by the oxidation of cholophæin. An alkaline solution of the latter gradually oxidises by exposure to the air, and, if then treated with acids, yields a green precipitate. Cholochloïn exists ready formed in ox-bile, and is abundant in that of birds, fishes, and amphibia.

Thudichum obtains the green pigment by allowing bile to stand in well-closed bottles for two years, whereupon a putrefactive decomposition ensues (p. 587), and cholochrome is precipitated, together with cholic acid and other substances. The precipitate, after decantation of the liquid, is put into a calico-bag and washed with water as long as the liquid will pass through; then boiled with alcohol and washed on a filter with large quantities of that liquid, which removes cholic acid and its salts, also fats and fatty acids. The colouring matter then remains, mixed with mucus, from which it may be freed by solution in carbonate of sodium. The alkaline solution, treated with hydrochloric acid, throws down a substance of a fine green colour, which however is probably still somewhat impure.

Cholochloïn is destitute of taste and odour. It does not melt when heated, but decomposes at a high temperature, leaving a large quantity of carbon. It is insoluble in cold, slightly soluble in boiling water; easily soluble in alkalis, also in alcohol.

According to Heintz, cholochloïn contains 60·04 per cent. C, 5·84 H, 8·53 N, and 25·59 O, whence is deduced the empirical formula $C^8H^9NO^{2\cdot5}$, requiring 60·38 C, 5·66 H, 8·80 N, and 25·16 O. Cholochloïn forms with baryta a green amorphous compound, containing 27·3 per cent. baryta.

The formulæ of cholophæin and cholochloïn, as deduced from their analyses, are very uncertain. Thudichum found 60 to 62 per cent. carbon in cholophæin from gall stones, and as much as 66 per cent. in that prepared from bile. Probably both modifications contain the same number of carbon-atoms, the green compound containing more oxygen than the brown: thus cholophæin = $C^8H^9NO^{2\cdot25}$, and cholochloïn $C^8H^9NO^{2\cdot5}$, or possibly $C^8H^9NO^2$ and $C^8H^9NO^3$.

CHOLOCHROMIC ACID. When nitric acid containing nitrous acid, is added to a dilute solution of cholochrome (either brown or green) in an aqueous alkali, the colour of the liquid changes to green, blue, violet, red, and finally to yellow. These changes of colour are connected with the formation of a non-azotised acid, which, according to Thudichum, may be obtained by passing nitrous acid vapours into water in which cholophæin is suspended. Effervescence then takes place, arising from evolution of nitrogen; the colour of the bile-pigment changes from brown to red; and on subsequently shaking it up with ether, a red solution is obtained, which on evaporation leaves a pink syrupy residue, consisting of the non-azotised acid, *cholochromic acid*. It dissolves easily in chloroform, and the solution, when evaporated in an atmosphere of coal-gas, and afterwards left to stand for some days in a flask filled with the same gas, deposits the acid, partly in flat rhombic octahedrons, partly in groups of radiating needles, partly as an amorphous mass.

Thudichum assigns to this acid the formula $C^{16}H^{18}O^7$, or $C^8H^9O^{3\cdot5}$. It should perhaps be $C^8H^8O^3$, in which case its formation from cholophæin might be represented by the equation:

$$C^8H^9NO^2 + HNO^2 = C^8H^8O^3 + N^2 + H^2O,$$

the reaction being that of nitrous acid on an amic acid (p. 168).

Cholochromic acid is nearly insoluble in cold water, but easily soluble in alcohol:

the solution has an acid reaction, and precipitates metallic salts. The lead-salt has a red, the silver-salt a pink colour.

CHOLOÏDANIC ACID. $C^{16}H^{24}O^{7}$ (?)—The residue in the retort obtained in treating choloïdic acid with nitric acid, separates on cooling into two layers, the upper of which is crystalline, and consists of choloïdanic acid. The crystalline crust is drained on a funnel containing pounded glass, and purified by recrystallisation from boiling water. Should the residue in the retort be merely a resinous mass, it must be further subjected to the action of nitric acid, which will finally convert it into the crystalline acid.

Choloïdanic acid crystallises in long hair-like prisms, which, after drying on paper, have the aspect of asbestos. It is nearly insoluble in cold water, and but sparingly soluble in boiling water; easily soluble in alcohol: the solutions are acid. It does not lose weight at 100° C.; but at a higher temperature it blackens and gives off an acrid acid vapour. It dissolves without alteration in hot nitric or hydrochloric acid.

Choloïdanic acid requires a large quantity of alkali to saturate it. The choloïdanates of the alkali and alkaline earth-metals are soluble in water; the rest are insoluble or sparingly soluble. They are all decomposed by washing with water.

CHOLOÏDIC ACID. $C^{24}H^{38}O^{4}$.—This acid was discovered by Demarçay, and has been further examined by Theyer and Schlosser and by Strecker (see references, p. 926). It is produced by the dehydration of cholic acid at 200° C., and, according to the observations of Gorup-Besanez and of Thudichum (p. 587), is one of the products of the putrefaction of bile: hence also it is found in gall-stones. It may be prepared directly from bile by boiling that liquid, dissolved in 12 to 15 pts. water, with excess of hydrochloric acid for three or four hours, and leaving the liquid to cool. Choloidïc acid then collects at the bottom in a solid mass, which must be several times melted with water to remove the hydrochloric acid, then pulverised, dissolved in a small quantity of alcohol, shaken up with ether to free it from cholesterin and margaric acid, and finally evaporated to dryness over the water-bath. If the action of the hydrochloric acid be too long continued, dyslysin is obtained instead of choloïdic acid (Demarçay). Choloïdic acid is likewise obtained by digesting bile with oxalic acid. (Theyer and Schlosser.)

Choloïdic acid is a white non-crystalline substance, which melts in boiling water without dissolving to a sensible amount. After drying it requires a heat of more than 150° C. to melt it. It is very soluble in alcohol; water renders the solution milky, and separates the acid in the form of a resin; the solution has an acid reaction. It is sparingly soluble in ether.

Choloïdic acid unites with bases and decomposes carbonates with aid of heat. The choloïdates of the alkali-metals are soluble in water and alcohol, insoluble in ether; they have a pure bitter taste without any sweetish after-taste. By evaporation they are obtained in the form of gummy masses. The salts of the earth-metals and heavy metals are insoluble or sparingly soluble in water, insoluble in alcohol, and are obtained in the form of plastic precipitates. The *barium-salt*, $C^{24}H^{37}BaO^{4}.2H^{2}O$ (at 120° C.) is insoluble in water and amorphous. The *silver-salt*, $C^{24}H^{37}AgO^{4}$ (at 100° C.), is a bulky white precipitate, which undergoes considerable contraction and coloration by drying.

Choloïdic acid is oxidised by strong nitric acid, yielding a great number of products. If 1 vol. choloïdic acid be treated in a tall vessel with 4 or 5 vol. strong nitric acid, the whole distilled to one-fifth, after the first violent action has subsided, cohobating if necessary, and the liquid, when the action has ceased, diluted with twice its bulk of water and again distilled, a distillate is obtained having a very acrid suffocating odour, arising from the presence of a heavy oil, consisting of nitrocholic acid, $CH^{2}N^{4}O^{5}$ (?), and cholacrol, while on the surface of the watery liquid there floats a light oil, which is a mixture of acetic, valeric, caprylic, and capric acid. The residue in the retort is a yellowish mixture of oxalic, cholesteric, and choloïdanic acids. (Redtenbacher, Ann. Ch. Pharm. lvii. 145.)

CHOLONIC ACID. $C^{26}H^{41}NO^{5}$. (Strecker, Ann. Ch. Pharm. lxvii. 1.—Mulder, *Untersuch. über die Galle.*—Gerh. iv. 722.)—This acid, which is homologous with glyco-hyocholic acid ($C^{27}H^{43}NO^{5}$), is produced by the action of strong acids upon glycocholic acid, from which it differs only by the elements of 1 at. water.

When a solution of glycocholic acid in strong sulphuric or hydrochloric acid is heated, it becomes turbid and yields oily drops, which solidify and become resinous on cooling; and by treating this resinous product with baryta-water, and decomposing the insoluble barium-salt with hydrochloric acid, cholonic acid is separated, and may be obtained in shining needles by crystallisation from alcohol.

Cholonate of Sodium, $C^{26}H^{40}NaNO^{5}$, is crystallisable.

In preparing cholonic acid by the action of hydrochloric on glycocholic acid, another acid is sometimes formed containing 1 at. H^2O less. (Strecker.)

CHONDRIN. $C^{16}H^{26}N^2O^7$. (J. Müller, Pogg. Ann. xxxviii. 305.—F. Simon, J. Chem. méd. i. 108.—Vogel, J. pr. Chem. xxi. 426.—Hopp, *ibid.* lvi. 129).—A substance resembling gelatin in many of its properties, and long confounded with it: its separate identity was first established by Müller.

Chondrin, like gelatin, does not occur ready formed in the organism, but is produced by boiling certain tissues with water. All permanent cartilages in a healthy state yield chondrin when boiled with water; so does bone-cartilage or ossein before ossification; but bone-cartilage after ossification yields gelatin by boiling: so likewise do the tendons, skin, calves' feet, hartshorn, isinglass, and fish scales; also the permanent cartilages when they become ossified by disease.

Chondrin may be prepared by boiling the cartilages of the ribs, larynx, or joints with water for about forty-eight hours, evaporating the liquid to a jelly, and treating this residue with ether to free it from fat. The cornea of the eye yields the same substance.

Chondrin, when dried, is a hard, horny, diaphanous substance, which softens to a jelly in cold water, and dissolves completely in boiling water; it is insoluble in alcohol and in ether. The aqueous solution, when boiled for a long time, yields a substance perfectly soluble in cold water, but resembling chondrin in all its other reactions.

Nearly all acids, even organic acids, precipitate chondrin from its aqueous solution. The precipitate formed by hydrochloric, sulphuric, nitric, phosphoric, phosphorous, chloric, or iodic acid, redissolves easily in excess of the acid; that formed by sulphurous, pyrophosphoric, hydrofluoric, carbonic, arsenic, acetic, tartaric, oxalic, citric, lactic, or succinic acid does not redissolve in excess of the acid employed. Strong sulphuric acid dissolves chondrin, forming a syrupy liquid, which, when diluted with water and boiled, yields leucine without glycocine (Hopp). Sulphurous acid slowly decomposes chondrin. Nitric acid, by prolonged action, converts it into *xantho-proteic acid.*

Alum, sulphate of aluminium, acetate and subacetate of lead, sulphate of copper, ferrous and ferric sulphates, ferric chloride, mercurous and mercuric nitrates, produce copious precipitates in a solution of chondrin, soluble for the most part in excess of the reagent. Ferrocyanide of potassium produces no precipitate. The precipitates formed by acetic acid, alum, and sulphate of aluminium dissolve completely on adding a sufficient quantity of acetate of potassium (or of sodium) or common salt. The precipitate formed by ferric sulphate redissolves on heating the liquid. Mercuric chloride does not precipitate a solution of chondrin; sometimes a slight turbidity is produced, owing apparently to the presence of a little gelatin.

Chondrin is especially distinguished from gelatin by its precipitation by alum, sulphate of aluminium, acetate of lead, the sulphates of iron and sulphate of copper, and by its non-precipitation by mercuric chloride. (See GELATIN.)

The aqueous solution of chondrin treated with chlorine, yields a precipitate containing $C^{16}H^{23}ClN^4O$ (?) (Schröder.)

By dry distillation chondrin yields the same products as gelatin (*q. v.*)

Mulder (Ann. Ch. Pharm. xxviii. 328) found in chondrin from human cartilage, 49·3 per cent. C, 6·6 H, 14·4 N, and 0·4 sulphur. Schröder also found in chondrin from the cartilages of the cow, 49·3 carbon and 6·6 hydrogen.

CHONDRODITE. *Hemiprismatic Chrysolite, Maclureite, Humite, Brucite* (in part).—A silicate of magnesium containing fluorine; sometimes occurring in small implanted crystals, but more frequently in crystalline grains or masses of somewhat granular structure, imbedded in granular limestone, as at Pargas in Finland, at Aker and Gulsjö in Sweeden, in Sussex County, New Jersey, in Orange County, New York, and other localities. The variety called *humite* is from Vesuvius, where it occurs in ejected masses of a kind of granite rock, together with olivine, mica, and magnetite.

The crystals belong to the trimetric system, and are often hemihedral in octahedral planes, producing forms of monoclinic character; $\infty P : \infty P = 94° 26'$. They are of three types, in which the axes have the following ratios:

	Macrodiagonal.		Brachydiagonal.		Principal axis.
Type I.	1·4678	:	1	:	1·0805
Type II.	1·5727	:	1	:	1·0805
Type III.	1·4154	:	1	:	1·0805

Compound crystals also occur. Cleavage indistinct. Specific gravity 3·118 to 3·22. Hardness 6 to 6·5. Colour yellow or brown, inclining to red and green, with waxy or glassy lustre; more or less translucent. It is scarcely fusible before the blowpipe, gives the reactions of fluorine when heated with sulphuric acid, and with fluxes the reactions of iron and silica. Dissolves in hydrochloric acid, with separation of gelatinous silica.

Analyses.—1. Seybert (Sill. Am. J. v. 336.—2, 3, 4. Rammelsberg (*Mineralchemie*, p. 443).—5. Fischer (Sill. Am. J. [2] ix. 85.—6, 7, 8. Rammelsberg (*loc. cit.*):

	SiO^2.	Mg^2O.	Fe^2O.	Fe^4O^3.	F.	
1. New Jersey . . .	32·66	54·00	—	2·33	—	HF 4·09; H^2O 1·0; K^2O 2·11
2. „ *yellow* . .	33·06	55·46	3·65	—	7·60	= 99·77
3. Pargas, *yellow* . .	33·10	56·61	2·35	—	8·69	= 100·75
4. „ *grey* . . .	33·19	54·50	6·75	—	9·69	= 104·13
5. New Jersey, *red* . .	33·35	53·05	5·50	—	7·60	= 99·50
6. *Humite*, type I. . .	34·80	60·08	2·40	—	3·47	= 100·75
				Ca^2O.		
7. „ type II. . .	33·26	57·94	2·30	0·70	5·04	Al^4O^3 = 1·06 = 100·38
8. „ type III. . .	36·67	56·83	1·67	—	2·61	= 97·78

These analyses lead to the formula $8Mg^2O.3SiO^2 = Mg^{16}Si^3O^{14} = 2Mg^2O.3Mg^4SiO^4$, wherein part of the oxygen is replaced by fluorine; or the mineral may be represented as made up of the two compounds:

$$Mg^{16}Si^3F^{28}, \text{ or } 16MgF.3SiF^4 = A$$

and:

$$Mg^{16}Si^3O^{14}, \text{ or } 8Mg^2O.3SiO^2 = B$$

in various proportions, namely:

Chondrodrite from Finland and North America $= A + 12B$
Humite from Vesuvius, type I. $= A + 18B$
„ „ type II. $= A + 27B$
„ „ type III. $= A + 36B$

Chondrodite occurs altered to serpentine at Sparta, New Jersey, with spinel and mica. (Dana, ii. 186.)

CHONDROGEN. A name applied to the tissues which yield chondrin when boiled with water, or rather to the substance which may be regarded as the basis of these tissues.

CHONDROITES. Concretions occurring in the cavities and channels of the animal body which are lined with mucous membranes, especially in the nose, gullet, tonsils, and bronchiæ: they are produced, under abnormal circumstances, from the secretion of these membranes, their nucleus being sometimes a solid body accidentally lodged in these cavities. They contain very variable quantities of water and animal matter, together with 50—80 per cent. of phosphate of calcium, 6—20 per cent. carbonate of calcium, 8—12 per cent. carbonate of magnesium, and small quantities of soluble salts. (Handw. d. Chem. ii. [2] 1196.)

CHONICRITE. A dense non-crystalline mineral from Elba, of specific gravity 2·91, hardness 3. Fracture conchoïdal. White. Translucent at the edges. Melts with tolerable facility to a greyish-white glass, evolving bubbles of gas at the same time; blue glass with cobalt-solution. Dissolves slowly in borax, yielding a glass slightly coloured by iron. Easily decomposed by concentrated hydrochloric acid, with separation of silica, not in the usual gelatinous state. According to Kobell's analysis, it contains 12·6 lime, 22·5 magnesia, 1·46 ferrous oxide, 17·12 alumina, 35·7 silica, and 9·0 water, a composition which may be approximately represented by the formula: $9(2M^2O.SiO^2).2(2Al^4O^3.3SiO^2) + 12\,aq.$, which by substituting $al = \frac{2}{3}$ Al, may be reduced to $3M^4SiO^4.2al^4SiO^4 + 4$ aq. (*Rammelsberg's Mineralchemie*, p. 858). Dana regards chonicrite as a variety of pyrosclerite (*q. v.*)

CHRISMATIN. A viscid translucent resin from Wettin near Halle, where it occurs as a coating on calcspar in a fissure. It has a shining lustre, and varies in colour from yellow to olive-green. Burns with flame and without odour. (Germar, Deutsche geol. Zeitschr. i. 40.)

CHRISTIANITE. See PHILLIPSITE.

CHROMATES. Chromic acid unites with nearly all bases. The salts are for the most part easily crystallisable and isomorphous with the corresponding sulphates. The chromates of the alkali-metals, and of strontium, calcium, and magnesium, are soluble in water: the others are insoluble, or sparingly soluble.

With the alkali-metals, chromic acid forms two series of salts, namely, neutral or normal chromates, $MCrO^2$, or $M^2O.Cr^2O^3$, which are yellow, and acid chromates, commonly called bichromates, $2MCrO^2.Cr^2O^3$, or $M^2O.2CrO^3$, which have an orange-red colour: a hyperacid chromate, or trichromate of potassium, $KCrO^2.Cr^2O^3$, or $K^2O.3Cr^2O^3$, is likewise known. These salts are produced, either by direct saturation of the base with chromic acid, or by igniting chromic oxide with an alkali and a nitrate or other oxidising agent.

The insoluble chromates are obtained by precipitation. Most of them are basic. Those which contain 3 at. basic metal to 1 at. chromium, may be called orthochromates, M^3CrO^3, or $3M^2O.Cr^2O^3$, the ordinary neutral chromates $MCrO^2$, which differ from them by M^2O, being metachromates.

A solution of an alkaline chromate gives with a salt of *barium*, *lead*, or *bismuth*, a yellow precipitate: with *mercurous* salts a brick-red, and with *silver*-salts, a red-purple precipitate: all these precipitates are soluble in nitric acid. Chromates boiled with excess of *hydrochloric* acid, yield a green solution of sesquichloride of chromium. A chromate of alkali-metal boiled with sulphuric acid and a reducing agent, such as *sugar*, *alcohol*, or *tartaric acid*, yields a purple or a green solution of a chromic alum. Chromates heated with *sulphuric acid and common salt*, give off yellowish-red vapours of oxychloride of chromium. The chromates of the less basic metals give off oxygen when ignited, and leave chromic oxide: the acid chromates of the alkali-metals leave a mixture of chromic oxide and neutral chromate. Insoluble chromates fused with *nitre*, yield chromate of potassium, which may be dissolved out by water.

Chromates in solution have a bitter metallic taste, and a poisonous action.

Chromates of Ammonium.—The *neutral salt* $(NH^4)CrO^2$, is obtained by evaporating a mixture of chromic acid with excess of ammonia, or by decomposing chromate of barium with sulphate of ammonium. Hirzel (Zeitschr. f. Pharm. 1852, p. 24), gradually adds oxychloride of chromium to excess of ammonia, and evaporates the solution at 60° C. Chromate of ammonium then crystallises out, and may be purified by recrystallisation. It forms lemon-yellow needles, permanent in the air; has a pungent taste and alkaline reaction. It is very soluble in water. Leaves chromic oxide when ignited.

Acid salt, $2NH^4CrO^2.Cr^2O^3$, or $(NH^4)^2O.2Cr^2O^3$.—Obtained by dividing a solution of chromic acid into two parts; saturating one with ammonia, then adding the other, and evaporating the whole over sulphuric acid. It forms orange-coloured crystals, permanent in the air, soluble in water, and yielding green chromic oxide when ignited. (Richmond and Abel, Chem. Soc. Qu. J. iv. 199.)

Darby (*ibid.* i. 20), by partially saturating chromic acid with ammonia and evaporating to the crystallising point, obtained a compound of ammonia with chromic anhydride $2NH^3.Cr^2O^3$, which may be regarded as a *chromamate of ammonium*, $\left.\begin{matrix}NH^2(Cr^2O^2)''\\ NH^4\end{matrix}\right\}O$, analogous to sulphamate of ammonium, $\left.\begin{matrix}NH^2(SO^2)''\\ NH^4\end{matrix}\right\}O$.

Hyperacid salt, $2NH^4CrO^2.5Cr^2O^3 + 10\,aq.$, or $(NH^4)^2O.6Cr^2O^3 + 10\,aq.$—Brown-yellow, very efflorescent salt, obtained in ill-defined crystals by evaporating a solution of chromic acid half neutralised with ammonia. (Rammelsberg, Pogg. Ann. xciv. 507.)

A compound of *chromic anhydride and sal-ammoniac*, $NH^4Cl.Cr^2O^3$, is obtained by adding oxychloride of chromium to a strong solution of sal-ammoniac, in crystals having the same form and aspect as the corresponding potassium-compound, but much more soluble in water. (Péligot, Ann. Ch. Phys. [2] lii. 267.)

Chromate of Barium.—The *neutral chromate*, $BaCrO^2$, is prepared by precipitating chromate of potassium with chloride of barium or baryta-water. It is insoluble in water, but dissolves, with reddish-yellow colour, in nitric, hydrochloric, or excess of chromic acid, and is precipitated from the solution by ammonia. It is decomposed by alkaline carbonates and sulphates, even at ordinary temperatures, and more quickly when heated. It is used as a pigment called *yellow ultramarine*.

Acid salt, $2BaCrO^2.Cr^2O^3$, or $Ba^2O.2Cr^2O^3$.—A concentrated solution of the neutral salt in chromic acid is decomposed by dilution, part of the salt being precipitated, while an acid salt remains in solution, and may be obtained by evaporation in yellowish-brown stellate crystals, containing $Ba^2O.2Cr^2O^3 + 2\,aq.$, which dissolve slowly in water, with separation of the neutral salt. (Babo, J. pr. Chem. lx. 60.)

Chromate of Bismuth.—When a solution of nitrate of bismuth is added to a moderately concentrated solution of acid chromate of potassium, leaving the latter slightly in excess, an egg-yellow, flocculent precipitate is formed, which afterwards becomes dense and crystalline. It consists of $3Bi^2O^3.2Cr^2O^3$ or $7Bi^2O^3.4Bi'''Cr^3O^6$. It is insoluble in water, may be dried without decomposition at 100° to 125° C., but acquires a dark green colour when ignited, and retains this colour after cooling. It dissolves in nitric or hydrochloric acid, forming a deep yellow liquid, which becomes turbid on dilution, from precipitation of basic nitrate or chloride of bismuth. If it be treated with a small quantity of acid, a yellow salt remains undissolved, consisting of $Bi^2O^3.2Cr^2O^3$ or $Bi^2O^3.4Bi'''Cr^3O^6$. The latter may also be obtained by precipitating acid chromate of potassium with a slightly acid bismuth-solution (J. Löwe, J. pr. Chem. lxvii. 288, 463). According to Pearson (*ibid.* lxviii. 255), the precipitate formed in the latter case is $Bi^2O^3.Cr^2O^3$, and is perfectly insoluble in water, so that it may be conveniently used for the estimation of bismuth.

Chromate of Cadmium.—A basic salt, $5Cd^2O.2Cr^2O^3 + 8aq.$, or $3Cd^2O.4CdCrO^2 + 8aq.$, is obtained as an orange-yellow precipitate, on mixing a cadmium-salt with neutral chromate of potassium. On adding ammonia, the salt $2NH^4CrO^2.(NH^3Cd)^2O + 2aq.$ is obtained, which crystallises in transparent, bright-yellow, six-sided pyramids, decomposing when exposed to the air or immersed in water.

Chromate of Calcium.—The *neutral* salt $CaCrO^2 + aq.$, is obtained by dissolving carbonate of calcium in aqueous chromic acid, or as a light yellow precipitate by mixing concentrated solutions of chromate of potassium and chloride of calcium. It is moderately soluble in water, insoluble in alcohol; gives off its water at 200° C., and is afterwards very sparingly soluble. The anhydrous salt is used as a pigment. The *acid-salt* obtained by dissolving the neutral salt in aqueous chromic acid and evaporating, forms red deliquescent crystals, containing $2CaCrO^2.Cr^2O^3 + 3aq.$

Chromate of Calcium and Potassium, $(KCa)Cr^2O^4 + aq.$, obtained by saturating acid chromate of potassium with hydrate of calcium, forms lemon-yellow, silky crystals.

Chromate of Cerium, $CeCrO^2$, is deposited as a yellow powder from a solution of carbonate of cerium in chromic acid. The filtrate yields on evaporation an acid salt in red prisms, soluble in water.

Chromate of Chromium.—The brown oxides of chromium intermediate between the sesquioxide Cr^4O^3, and chromic anhydride, Cr^2O^3, may be regarded as compounds of these two in various proportions, that is, as chromates of chromium. (See **Chromium, Oxides of.**)

Chromate of Cobalt.—Solutions of cobalt-salts form with chromate of potassium, a light red-brown precipitate containing, according to Sarzeau and Malaguti (Ann. Ch. Phys. [3] ix. 431), $Co^2CrO^3 + 2aq.$, which is the formula of an orthochromate.

Chromates of Copper.—When impure cupric hydrate is immersed in a strong solution of chromic acid, a brown solution is formed which deposits a brown powder, probably a tetrabasic salt, $4Cu^2O.2Cr^2O^3$, or $2Cu^2O.4CuCrO^2$ (Dröge, Ann. Ch. Pharm. ci. 89). The solution filtered through asbestos, and evaporated over oil of vitriol, yields, after a while, green crystals, consisting, according to Kopp (*ibid.* lvii. 386), of cupric sulphate in which part of the sulphuric acid is replaced by chromic acid (H^2SO^4 by $H^2Cr^2O^4$, or S by Cr^2). The mother-liquor decanted therefrom, is free from sulphuric acid, and yields by evaporation, acid cupric chromate, $2Cu^2CrO^2.Cr^2O^3 + 2aq.$, in brown-black, deliquescent crystals, soluble in alcohol and in ammonia. The aqueous solution deposits on boiling a brown insoluble salt. The crystals give off their water at 100° C., and at a red heat the salt is completely decomposed. The tetrabasic salt above mentioned is deposited as a chocolate-brown precipitate, containing 5 at. water, on mixing a boiling solution of neutral chromate of potassium with basic sulphate of copper. (Malaguti and Sarzeau.)

An *ammonio-chromate of copper*, $5NH^3.Cu^2O.4CuCrO^2 + aq.$, is obtained in dark green prismatic crystals, by passing ammonia-gas into water in which tetrabasic chromate of copper is suspended, and cooling the liquid below 0° C. It soon gives off its ammonia when exposed to the air: and is resolved by water into insoluble basic chromate of copper, and a basic ammonio-chromate which dissolves in the water with emerald-green colour. The same basic ammonio-chromate is obtained by treating acid cupric chromate with ammonia.

Chromate of Copper and Potassium, $K^2O.3Cu^2O.3Cr^2O^3 + 3aq.$, or $CuHO.(KCu^2Cr^2O^6 + aq.$, is obtained by treating recently precipitated cupric hydrate with solution of acid chromate of potassium, or by mixing a solution of cupric sulphate with acid chromate of potassium, and gradually adding caustic potash. The product is a light brown powder, consisting of microscopic, translucent, six-sided tablets, nearly insoluble in water, but dissolving with deep green colour in ammonia or carbonate of ammonium. The solution, if saturated while hot, deposits on cooling green prisms having a strong lustre.

Chromate of Glucinum is a yellow insoluble precipitate.

Chromate of Iron.—Aqueous chromic acid digested with moist ferric hydrate, yields a brown solution, containing $Fe^4O^3.4Cr^2O^3$. The solution is not rendered turbid either by dilution or by boiling, and yields on evaporation a brown resinous residue, soluble in water and in alcohol. The *basic salt* is a brown powder, which is resolved by water into ferric oxide and chromic acid.

Chromates of Lead.—The neutral or metachromate, $PbCrO^2$, is found native as *Red-lead ore*, *Crocoisite*, or *Lehmannite*, in monoclinic prisms, in which the ratio of the orthodiagonal, clinodiagonal, and principal axis is as 1·041 : 1 : 0·96, and the inclination of the principal axis to the clinodiagonal, 77° 30′. The predominant faces are generally ∞P and $-P$. Cleavage most distinct parallel to ∞P. Specific gravity 5·9 to 6·1. Hardness 2·5 to 3. The crystals are translucent and of a yellow colour, with various shades of bright hyacinth-red; streak orange-yellow. Sectile. It occurs in decomposed gneiss or granite, at Nischne Tagilsk in the Ural, in Brazil, at Retzbanya in Hungary, at Moldawa in the Bannat, and in Luzon, one of the Phillippine Isles.

Neutral chromate of lead is obtained as a light yellow insoluble precipitate, by mixing a dilute solution of a neutral lead-salt with neutral or acid chromate of potassium; concentrated solutions yield an orange-yellow precipitate. It may also be obtained by decomposing sulphate or chloride of lead with chromate of potassium. It is insoluble in water, slightly soluble in nitric acid, easily in potash. At a moderate heat, it melts without decomposition to a brown mass, exhibiting a radiated structure when cold, and yielding a dark yellow, slightly hygroscopic powder. At a full red heat, it gives off oxygen, and is reduced to a mixture of basic chromate of lead and chromic oxide. Heated in a stream of hydrogen gas, it gives up 12 per cent. oxygen, and is reduced to a mixture of chromic oxide and metallic lead, which when heated in a stream of oxygen takes up 7 per cent. of that gas. (On the use of chromate of lead in organic analysis, see pp. 227, 232.)

Chromate of lead is much used as a pigment, known as **chrome-yellow**, also *lemon-yellow, Leipzig yellow, Paris yellow*, &c. The finer sorts are prepared by precipitation, the commoner kinds by decomposing carbonate, chloride, or sulphate of lead (obtained as a by-product in the preparation of alum-mordants), with chromate of potassium. According to Anthon, 100 pts. sulphate of lead require for decomposition 25 pts. of red chromate of potassium, and 100 pts. chloride of lead require 27 pts. of red chromate. Chrome-yellow exhibits various shades of red and yellow, according to its mode of preparation: it is often mixed with chalk, gypsum, heavy spar, clay, sulphate of lead, &c. *Cologne yellow* is a mixture of chromate and sulphate of lead with sulphate of calcium, obtained by precipitating a mixture of the nitrates of lead and calcium with a mixture of sulphate of sodium and chromate of potassium. It is not altered by exposure to air or light; sulphuretted hydrogen turns it brown; protochloride of tin and sulphurous acid reduce it; alkalis turn it orange or red, by formation of basic chromate of lead. It is used as an oil or water-colour, for lacquering, and may be mixed with many other colours without decomposition; with Prussian blue it forms a green mixture, called **chrome-green**, or **green cinnabar**. In calico-printing, chrome-yellow is formed on the fabrics themselves, by first steeping them in a solution of lead-salt, then in chromate of potassium. For dyeing silk and wool it is not so well adapted.

Basic Chromate of Lead.—A *dibasic* or *tetraplumbic chromate*, $2Pb^2O.Cr^2O^3 = Pb^2O.2PbCrO^2$, known in the arts as **chrome-red**, is produced from the neutral chromate by digesting it with caustic alkalis, or with levigated oxide of lead, or by boiling it in the recently precipitated state with neutral chromate of potassium, or by fusing it with nitre. It is of a deep orange or red colour, according to the mode of preparation. The finest vermilion-red chromate is formed when 1 pt. of chrome-yellow is thrown into 5 pts. of nitre in a state of fusion, and the resulting chromate of potassium, together with the excess of nitrate, dissolved out by water: the basic chromate of lead then remains in the form of a crystalline powder (Liebig and Wöhler). An orange pigment may be obtained very economically, by boiling the sulphate of lead, which is a waste product in making acetate of alumina from alum by means of acetate of lead, with a solution of chromate of potassium. The basic chromate of lead, forms a beautiful orange upon cloth, which is even more stable than the yellow chromate, not being acted upon by either alkalis or acids. One method of dyeing chrome-orange, is to fix the yellow chromate of lead in the calico, by dipping it successively in acetate of lead and acid chromate of potassium, and then washing it. This should be repeated, in order to precipitate a considerable quantity of the chromate in the calico. A milk of lime is then heated in an open pan; and when it is at the point of ebullition, the yellow calico is immersed in it, and instantly becomes orange, being deprived of a portion of its chromic acid by the lime, which forms a soluble chromate of calcium. At a lower temperature, lime-water dissolves the chromate of lead entirely, and leaves the cloth white.

A *sesquibasic* or *hexplumbic chromate*, $3Pb^2O.2Cr^2O^3 = Pb^2O.4PbCrO^2$, is found native as *Melanochroïte, Phœnicite*, or *Phœnikochroite*, at Beresof in the Ural, associated with crocoisite, vauquelinite, pyromorphite, and galena. It occurs in tabular crystals, apparently belonging to the trimetric system, reticularly interwoven; cleaving perfectly in one direction; also massive. Specific gravity 5·75. Hardness 3 to 3·5. It has a resinous or adamantine, glimmering lustre, cochineal or hyacinth-red colour, becoming lemon-yellow on exposure to the air. Streak brick-red. Subtranslucent or opaque.

A *chromate of lead and copper*, of analogous composition, viz. $\left.\begin{matrix}Pb\\Cu^4\end{matrix}\right\}{}^2O.4\begin{pmatrix}Pb^3\\Cu^4\end{pmatrix}CrO^2$, called *Vauquelinite*, occurs at Beresof, at Pont Gibaud in the Puy de Dôme, and with the crocoisite of Brazil, in monoclinic crystals, usually minute and irregularly aggregated; also reniform or botryoïdal, and granular; amorphous. Specific gravity 5·5 to 5·78. Hardness 2·5 to 3. It has a dark green to brown colour, sometimes nearly black, with adamantine or resinous lustre, often faint. Streak, siskin-green or brownish. Faintly translucent or opaque. Fracture uneven. Rather brittle. (Dana, ii. 360.)

CHROMATE OF LITHIUM, $LiCrO^2$, crystallises in orange-yellow, oblique rhombic prisms, easily soluble in water.

CHROMATE OF MAGNESIUM, $2MgCrO^4 + 7aq.$, obtained by evaporating a solution of magnesia in chromic acid, forms lemon-yellow crystals isomorphous with sulphate of magnesium. Specific gravity = 1·66 at 15° C.

Chromate of Magnesium and Ammonium, $Mg(NH^4)Cr^2O^4 + 3aq.$, is isomorphous with the corresponding sulphate.

CHROMATES OF MANGANESE.—A *manganic* salt, $3(Mn^4O^3.Cr^2O^3).Cr^4O^3 + 6aq.$, is precipitated on mixing sesquichloride of manganese with chromate of potassium. (Fairrie, Chem. Soc. Qu. J. iv. 300.)

A *basic manganous chromate*, $2Mn^2O.Cr^2O^3 + 2aq. = Mn^2O.2MnCrO^2$, is obtained as a crystalline precipitate on mixing manganous sulphate with neutral chromate of potassium. It is brown, translucent, and dissolves with orange-yellow colour in sulphuric and nitric acids (Warington, *L'Institut*, No. 513, p. 366.—Reinsch, Pogg. Ann. lv. 97). According to Fairrie, it contains chromic oxide.

CHROMATES OF MERCURY.—*Mercuric metachromate*, $HgCrO^2$, is obtained by boiling equal parts of chromic anhydride and yellow mercuric oxide in water, and gradually evaporating till the mercuric oxide disappears, and red crystals are formed in its place: the mother-liquor yields an additional quantity by concentration. It forms dark garnet-red rhombic prisms, becoming darker-coloured when heated. They are decomposed by water, even in the cold, and completely when heated, yielding free chromic acid and amorphous *mercuric orthochromate*, Hg^3CrO^3. They dissolve readily in hydrochloric acid, and potash added to the solution throws down yellow mercuric oxide, or perhaps the orthochromate. Strong nitric acid converts them, in the cold, into an amorphous yellow compound, a large portion however dissolving; moderately strong nitric acid and dilute sulphuric acid act in the same manner, excepting that a larger quantity of the yellow compound remains undissolved.

Mercuric orthochromate, Hg^3CrO^3, or $3Hg^2O.Cr^2O^3$, is obtained as a brick-red powder on adding mercuric nitrate to acid chromate of potassium; or by boiling yellow mercuric oxide with chromate of potassium (Millon). It is also produced, together with a less basic salt, by precipitating the mother-liquor of the metachromate with carbonate of sodium. On boiling the precipitate with soda-ley, an amorphous, yellow, heavy powder is precipitated, which appears to consist of $7Hg^2O.2Cr^2O^3$, or $Hg^2O.4Hg^3CrO^3$. The same salt appears also to be obtained by boiling recently precipitated mercuric oxide with acid chromate of potassium, till it is converted into a brick-red powder, washing this powder repeatedly by decantation, and heating it with moderately strong nitric acid. It dissolves in strong nitric acid only when recently precipitated; strong sulphuric acid, with aid of heat, converts it into white mercuric sulphate; hydrochloric acid does not dissolve it. (Geuther, Ann. Ch. Pharm. cvi. 244.)

A *tetrabasic mercuric chromate*, $4Hg^2O.Cr^2O^3$, or $3Hg^2O.2HgCrO^2$, of dark violet or brown colour, is said to be obtained by boiling red mercuric oxide with chromate of potassium. When equivalent quantities of basic mercuric chromate and solution of cyanide of mercury and potassium are boiled together for some time, oxycyanide of mercury separates first, and afterwards a compound containing $KHgCy^2$ and $HgCrO^2$. (Geuther.)

Mercurous chromate, $Hg^4O.Cr^2O^3 = HhgCrO^2$, is obtained as a brilliant red crystalline powder, by boiling the basic salt next to be described, with a small quantity of dilute nitric acid, or the double salt of cyanide of mercury and chromate of potassium with mercurous nitrate.

Basic mercurous chromate, $2Hg^4O.Cr^2O^3 = Hhg^2O.2HhgCrO^2$, is obtained as a brick-red powder by precipitating mercurous nitrate with chromate of potassium. Both these salts when heated, give off oxygen and mercury, and leave chromic oxide of a beautiful green colour.

CHROMATES OF MOLYBDENUM.—The neutral salt dissolves in water with yellow colour, and yields by spontaneous evaporation, white, scaly, needle-shaped crystals. The acid salt dries up to an amorphous brown mass. The solution of either salt mixed with ammonia yields a precipitate of basic chromate of molybdenum.

CHROMATE OF NICKEL.—Hydrate and carbonate of nickel dissolve in chromic acid with yellowish-red colour, forming an acid salt (Malaguti and Sarzeau). The solution of a neutral nickel-salt boiled with neutral chromate of potassium, yields an amorphous precipitate, consisting of $3Ni^2O.2NiCrO^2 + aq.$, and having the colour of Spanish tobacco. If this or the soluble salt be covered with ammonia, a heavy yellow-green crystalline powder, $3NH^3.NiCrO^2 + \frac{2}{3}aq.$ is formed, which is decomposed by air and water.

Chromates of Potassium.—Three of these salts are known, viz.:

Neutral chromate, monochromate, or metachromate of potassium	$K^2O.Cr^2O^3$, or $KCrO^2$
Acid or dichromate	$K^2O.2Cr^2O^3$, or $2KCrO^2.Cr^2O^3$
Hyperacid or trichromate . . .	$K^2O.3Cr^2O^3$, or $KCrO^2.Cr^2O^3$.

The neutral and acid salts are important articles of manufacture, being extensively used in dyeing and calico-printing, and for the preparation of chrome-yellow and chrome-red; also as oxidising agents: the acid salt is most used, because it contains a larger percentage of chromic acid.

The chromates of potassium are prepared by igniting chrome-iron ore, a compound of sesquioxide of chromium and protoxide of iron, in contact with alkalis and oxidising agents, and lixiviating the fused mass with water. A yellow solution is thus obtained, from which, by quick evaporation, the neutral salt is thrown down in yellow crystalline granules; and by redissolving this granular salt in water, and leaving the solution to evaporate slowly, the salt is obtained in regular crystals. The concentrated solution of the neutral chromate, treated with one of the stronger acids, yields the acid chromate; and by evaporating the solution to the crystallising point, picking out the crystals of acid chromate from the nitrate or other potassium-salt formed at the same time, and recrystallising several times, the acid chromate is obtained in large tabular crystals of an orange-red colour

The process first adopted for the preparation of chromate of potassium, was to calcine the ore with nitre; but it may be rendered more economical by substituting carbonate of potassium (pearlash) for a portion of the nitre; and still more by dispensing with the nitre altogether, and effecting the oxidation of the chromic oxide by means of air admitted into the reverberatory furnace in which the calcination takes place. But whether nitre be used or not, the oxidation is still found to be imperfect, because the alkali fuses into a thin liquid, and the chrome-iron ore, being very heavy, sinks to the bottom, and thus remains to a great extent unaltered, especially when the oxidation is effected by contact with the air, an inconvenience which is but imperfectly obviated even by continual stirring. But by adding lime to the mixture, as first proposed by Stromeyer, it is rendered less fluid, and a moderate amount of stirring then suffices to keep it well mixed, so that the oxidation takes place with much greater facility. It is found, indeed, that when lime is added, the nitre may be altogether dispensed with, and its place supplied by carbonate, sulphate, or chloride of potassium, which are cheaper. Mr. Tilghman has patented a process for the use of felspar as a source of alkali, 4 pts. by weight of that mineral being calcined in a reverberatory furnace, with 4 pts. of lime or an equivalent quantity of chalk, and 1 pt. of chrome-iron ore. Mr. Booth of Philadelphia subjects the chrome-iron ore to a preliminary ignition with coke or other carbonaceous material, whereby the iron is reduced to the metallic state, then removes the iron by means of dilute sulphuric acid, and subjects the chromic oxide thus purified, to calcination with alkali and nitre; by this means, the portion of oxygen which would be expended in converting the protoxide of iron into sesquioxide, is rendered available for the production of chromic acid. The production of sulphate of iron incidental to the process tends to defray the expense.

Jacquelain prepares acid chromate of calcium from chrome-iron ore, and converts that salt into acid chromate of potassium by double decomposition. The chrome-ore, after being ground to very fine powder and sifted, is mixed with chalk in rotating barrels, and the mixture is spread in a layer 1½ to 2 inches thick on the hearth of a reverberatory furnace, heated to bright redness for nine or ten hours, and stirred at least every hour. After this treatment, the mixture has a yellowish-green colour, dissolves in hydrochloric acid, and with the exception of a certain quantity of sand, consists essentially of *neutral chromate of calcium* ($CaCrO^2$) mixed with oxide of iron. This mass is ground to powder by millstones; the powder is stirred up with hot water, and sulphuric acid is added till a slight acid reaction becomes apparent. The neutral chromate of calcium is thereby converted into *acid chromate*. The liquid also contains sulphate of iron, which is precipitated in the same vessel by stirring up with chalk, which does not affect the chrome-salt. The precipitate having settled down, the clear solution of acid chromate of calcium containing a little sulphate is run off, and may be used, without further treatment, for preparing by double decomposition, acid chromate of potassium, chromate of lead, either neutral or basic, and chromate of zinc. To obtain acid chromate of potassium, the solution of acid chromate of calcium is treated with carbonate of potassium, which throws down carbonate of calcium in a form easy to wash, leaving acid chromate of potassium in solution, which may then be evaporated and crystallised. The chief advantages of this process are that it requires less stirring than the ordinary method, even when lime is used, and that it avoids the loss of alkali, which always ensues (to the amount of 9 or 10 per cent.) when the mixture of chrome-iron ore and potassium-salt is raised to a bright red heat. (For further details on the manufacture of alkaline chromates, see *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 684; and *Richardson* and *Watts' Chemical Technology* i. [4] 59.)

a. *Neutral Chromate of Potassium*, $KCrO^2$.—This salt is obtained by neutralising the acid chromate with an alkali, or by igniting chrome-iron ore with excess of alkali (p. 936). It crystallises in double six-sided pyramids, belonging to the trimetric system, and isomorphous with sulphate of potassium: hence it is capable of crystallising with the latter in all proportions. It has a pale lemon-yellow colour, an alkaline reaction, and a cooling, persistently bitter taste: it is poisonous even in small doses. Specific gravity 2·705 (Kopp). 100 pts. of water at 15° C. dissolve 48½ pts. of this salt, and in boiling water it dissolves in all proportions. It possesses great colouring power, 1 pt. of it imparting a distinct yellow tint to 400,000 pts. of water, and a deep yellow colour to 20 pts. of nitre when crystallised therewith. It is insoluble in alcohol, and is precipitated by alcohol from its aqueous solution. The solution yields by evaporation, red crystals of the acid chromate, and the alkaline mother-liquor afterwards deposits yellow crystals of the neutral salt. The neutral chromate acquires a transient red colour when heated, melts at a higher temperature, and solidifies in the crystalline form on cooling. It is not decomposed by simple ignition, but when heated to redness in contact with charcoal, sulphur, sal-ammoniac, and other reducing agents, it forms chromic oxide together with a potassium-salt. It is decomposed by acids, even by carbonic acid, yielding the acid chromate of potassium. Sulphydric acid and sulphide of potassium decompose it, with formation of chromic hydrate; sulphurous acid forms at first brown oxide of chromium, then a chromic salt. According to Schweizer (J. pr. Chem. xxxix. 267), arsenious acid forms with it a gelatinous mass, which after drying at 100° C. contains $4K^2O.3Cr^4O^3.3As^2O^3.10H^2O$.

b. *Acid Chromate*, $K^2O.2Cr^2O^3 = 2KCrO^2.Cr^2O^3$. *Bichromate of Potash, Red Chromate of Potash.*—This salt is obtained by treating the solution of the neutral salt with one of the stronger acids, or by precipitating a solution of acid chromate of calcium with carbonate of potassium (p. 936). It separates by rapid evaporation as an orange-coloured crystalline powder, and by slower evaporation in splendid garnet-red tables or prisms, belonging to the triclinic system. It is permanent in the air, reddens litmus, has a cooling, bitter, and metallic taste. Its powerful oxidising properties cause it to exert a poisonous action on the animal economy, both internally and externally: the workmen engaged in its manufacture suffer greatly from malignant ulcers. It dissolves in 10 pts. of water at 15° C., much more abundantly in boiling water; it is insoluble in alcohol. It melts at a heat below redness to a transparent red liquid, which by slow cooling yields large fine crystals, having the same form as those obtained from the aqueous solution, but crumbling to powder at lower temperatures. At a white heat, it gives off oxygen, leaving neutral chromate mixed with chromic oxide. Heated with charcoal, it is reduced, with slight detonation; paper or calico saturated with the solution and dried burns like tinder when heated. Paper thus saturated acquires a darker colour by exposure to light, but remains unaltered in the dark: hence it may be used in photography. Heated with strong sulphuric acid it gives off oxygen (about 16 per cent. by weight), and yields water and potassio-chromic sulphate (chrome-alum).

$$K^2Cr^4O^7 + 4H^2SO^4 = 2[(Cr^2)'''KS^2O^8] + 4H^2O + O^3.$$

It is also reduced when heated with sulphur or sal-ammoniac. Sulphydric acid precipitates from its solution a mixture of chromic oxide and sulphur. Sulphurous acid colours it green without forming a precipitate, from formation of chromic sulphate and hyposulphate. A solution of the salt in boiling hydrochloric acid deposits on cooling chromo- chloride of potassium (p. 938). The solution of acid chromate absorbs a considerable quantity of nitric oxide, acquiring a dark colour, and depositing after a while brown oxide of chromium.

A concentrated solution of the acid chromate mixed with strong-sulphuric acid, yields a deep red precipitate of chromic acid.

A double salt, composed of *sulphate* and *acid chromate of potassium*, is obtained by mixing a concentrated solution of the acid chromate with a quantity of sulphuric acid less than sufficient to convert the potassium into acid sulphate. It crystallises on cooling in stellate needles. (Reinsch.)

c. *Hyperacid Chromate*, or *Trichromate of Potassium*, $K^2O.3Cr^2O^3$, or $KCrO^2.Cr^2O^3$, separates from a solution of the acid chromate in ordinary nitric acid prepared at 60° C., in dark red nacreous prisms, of specific gravity 3·631, which blacken when exposed to the air, and melt at 145°—150° C. (Graham.)

Chromate of Potassium and Ammonium, $K(NH^4)Cr^2O^4$, crystallises from a concentrated solution of acid chromate of potassium saturated with ammonia, and cooled by a freezing mixture, or evaporated over lime, in crystals apparently isomorphous with sulphate of potassium: when exposed to the air, it gives off ammonia and turns reddish-yellow. (Johnson, J. pr. Chem. lxii. 261.)

Chromate of Potassium with Mercuric Chloride, $KCrO^2.2HgCl$, is obtained by mixing the component salts in equivalent proportions, and adding sufficient hydrochloric acid to redissolve the precipitate first produced. Small slightly reddish crystals, which form a yellow solution in water. Another salt, $2KCrO^2.Cr^2O^3.2HgCl$, is obtained in red spicular crystals, by mixing acid chromate of potassium and mercuric chloride in equivalent proportions, and leaving the solution to evaporate. (Darby, Chem. Soc. Qu. J. i. 24.)

Chromate of Potassium with Mercuric Cyanide, $2KCrO^2.3HgCy$.—Light yellow laminar crystals, obtained by evaporating a solution of 1 pt. neutral chromate of potassium and 3 pts. cyanide of mercury. (Darby.)

Chromo-chloride of Potassium, $KCl.Cr^2O^3 = \left.\begin{matrix}(Cr^2O^2)'' \\ K\end{matrix}\right\}\begin{matrix}O \\ Cl\end{matrix}$. This salt, which is analogous in composition to the triacid chromate $KCrO^2.Cr^2O^3$, is obtained by dissolving together, with aid of heat, 3 pts. acid chromate of potassium, and 4 pts. hydrochloric acid, avoiding evolution of chlorine. It crystallises in flat, red, rectangular prisms, and is decomposed by solution in water.

CHROMATES OF SILVER.—The *neutral salt*, $AgCrO^2$, is obtained as a red precipitate by decomposing neutral chromate of potassium with nitrate of silver, or by boiling the acid silver-salt with water, whereby it is partly resolved into chromic acid and the neutral chromate, which then separates in crystals green by transmitted light, and yielding a red powder. A solution of the acid salt in ammonia deposits the neutral salt on evaporation, in dark green metallic crusts.

Acid Chromate of Silver, $2AgCrO^2.Cr^2O^3$, is obtained by immersing metallic silver in solution of acid chromate of potassium mixed with sulphuric acid, or by precipitating the same acidulated solution with a silver-salt. It has the colour of carmine, is partly soluble in water, and crystallises therefrom in triclinic prisms, having a dark brown colour, red by transmitted light, and yielding a red powder.

Ammonio-chromate of Silver, $2NH^3.AgCrO^2$, separates from a hot solution of chromate of silver in ammonia, in yellow, square prisms, isomorphous with the corresponding salts of sulphuric and selenic acid: they give off ammonia when exposed to the air.

CHROMATES OF SODIUM.—Two of these salts are known, namely, the *neutral chromate*, $NaCrO^2$, and the *acid chromate*, $2NaCrO^2.Cr^2O^3$. They are analogous in all respects to the neutral and acid chromates of potassium, and may be prepared in like manner. The neutral salt, which may also, according to Johnson (J. pr. Chem. lxii. 161), be obtained by saturating a solution of acid chromate of potassium with carbonate of sodium, and leaving it to evaporate at 0° C., crystallises at low temperatures in yellow transparent crystals, containing $NaCrO^2.5aq.$, isomorphous with Glauber salt: they melt at the heat of the hand, deliquesce rapidly in the air, are easily soluble in water, sparingly in alcohol, and when immersed in alcohol, become opaque from loss of water. The aqueous solution evaporated at temperatures above 30° C., deposits the anhydrous salt.

Acid chromate of sodium, $2NaCrO^2.Cr^2O^3$, forms thin, hyacinth-red prisms, very soluble in water.

CHROMATE OF STRONTIUM.—Light yellow powder, obtained by precipitation; soluble in hydrochloric, nitric, and chromic acid; rather more soluble in water than the barium-salt.

CHROMATES OF TIN.—Stannic chloride forms with chromate of potassium a yellow precipitate, which becomes brownish-yellow and translucent when dry, and passes into violet stannic chromate when ignited.

Stannous chromate is precipitated in yellow curdy flocks, when stannous chloride is added with stirring to excess of chromate of potassium. If the contrary course be adopted, a greenish-white precipitate is formed, perhaps consisting of chromic stannate. The salt leaves a violet residue when ignited.

URANIC CHROMATE.—Uranic nitrate forms an ochre-yellow precipitate with neutral chromate of potassium. The yellow rough-tasting solution of uranic carbonate in aqueous chromic acid, yields small fiery-red crystals. The salt melts at a gentle heat, with partial decomposition.

Chromate of Vanadium.—The brownish-yellow solution of vanadic hydrate in aqueous chromic acid, yields on evaporation, a shining, dark brown, varnish-like mass, which dissolves partially in water, forming a yellow liquid.

Chromate of Yttrium.—Soluble salt, crystallising in small yellow prisms.

Chromate of Zinc.—Sulphate of zinc, mixed with neutral chromate of potassium, forms a yellow precipitate of a basic salt. Malaguti and Sarzeau, by treating carbonate of zinc with pure chromic acid, obtained a yellow crystalline basic salt, containing $4Zn^2O.Cr^2O^3 + 5$ aq., or $Zn^2CrO^4.ZnHO + 2$ aq. By boiling this salt with chromic acid as long as anything dissolves, the same chemists obtained a soluble non-crystalline salt, $2Zn^2O.3Cr^2O^3$, or $4ZnCrO^2.Cr^2O^3$.

Ammonio-chromate of Zinc.—The tetrabasic salt repeatedly treated with ammonia, yields yellow cubic crystals, containing $2(ZnCrO^4.NH^3) + 5$ aq. Soluble chromate of zinc, $2Zn^2O.3Cr^2O^3$, treated with excess of ammonia and then with alcohol, yields a copious precipitate, consisting of microscopic needles containing $5NH^3.4ZnCrO^2 + 9$ aq. (Malaguti and Sarzeau.)

Chromate of Zinc and Potassium.—The precipitate formed by chromate of potassium in sulphate of zinc, if left for some time under the liquid, changes to an orange-yellow powder, consisting of the double salt. It is sparingly soluble in cold water, but imparts a yellow colour to a large quantity of the liquid; in boiling water, it dissolves with deep yellow colour, with separation of a lighter coloured basic salt. When ignited, it leaves a dark brown residue, from which water extracts neutral chromate of potassium, leaving a compound of sesquioxide of chromium and oxide of zinc. (Handw. d. Chem. ii. [2] 1246.)

CHROME ALUM. This name is applied to the double sulphates of chromium and the alkali-metals, analogous in composition to common alum and isomorphous therewith, *e.g. potassio-chromic sulphate*, $K(Cr^2)'''(SO^4)^2 + 12H^2O = \left.\begin{matrix}(S^2O^4)^{iv} \\ K.(Cr^2)'''\end{matrix}\right\} O^4 + 12H^2O$.

CHROME GREEN. A name applied sometimes to green oxide of chromium, sometimes to the pigment produced by mixing chrome yellow with Prussian blue. (See Chromate of Lead, p. 934.)

CHROME IRON ORE. *Chromic Iron, Chromate of Iron, Chromeisenstein, Eisenchrom, Ferrochromate.*—This mineral, which is the most abundant ore of chromium, usually occurs massive, with fine granular or compact structure, forming veins or imbedded masses in serpentine; more rarely in regular octahedrons, with imperfect cleavage parallel to the octahedral faces. Specific gravity 4·32 to 4·57. Hardness 5·5. Colour brownish-black, or iron-black. Streak brown. Lustre submetallic, inclining to waxy. Opaque. Brittle, with conchoïdal or uneven fracture. Sometimes magnetic. Before the blowpipe it does not fuse, but becomes more strongly magnetic. With borax or phosphorus-salt it fuses with difficulty, but completely, to a beautiful green globule.

Chrome iron ore belongs to the spinel group of minerals, whose general formula is $M^2O.R^4O^3$ or $\left.\begin{matrix}M' \\ (R^2)'''\end{matrix}\right\} O^2$. The monatomic metal is chiefly iron, but magnesium is generally also present in considerable quantity, and in some specimens a small portion of the chromium appears to exist as chromosum. The sesqui-atomic metal R is principally chromium, but it is replaced to a considerable extent by aluminium, and sometimes also by iron (ferricum), so that the general formula of the mineral is $\left.\begin{matrix}Fe;\ Mg;\ Cr; \\ Cr^2;\ Al^2;\ Fe^2;\end{matrix}\right\} O^2$. From the numerous analyses that have been made of it, we select the following as samples of the different varieties: *a*, from Baltimore, Maryland, by Abich (Pogg. Ann. xxxiii. 335); *b*, from Volterra, Tuscany, by Bechi (Sill. Am. J. [2] xiv. 62); *c*, from Texas, Lancaster county, Pennsylvania, by Franke (*Rammelsberg's Mineralchemie*); *d*, from the same, by Garrett (Sill. Am. J. [2] xiv. 46); *e*, crystallised, from Baltimore, by Abich (*loc. cit.*); *f*, from Beresow, Siberia, by Moberg (J. pr. Chem. xliii. 119):

Besides the above localities, chrome-iron ore is found in the islands of Unst and Fetlar in the Shetland group, in the Département du Var in France, in Silesia and Bohemia, at Röraas in Norway, near Kraubat in Syria, abundantly in Asia Minor and the Eastern Urals, and in several parts of North America. It assists in giving the green colour to verd-antique marble. The ore used in this country is obtained chiefly from the Shetland Isles, Norway, and Baltimore, the quantity amounting to 2000 tons annually. (Dana, ii. 106; *Rammelsberg's Mineralchemie*, p. 172.)

CHROME-MICA. This name was given by Breithaupt to an emerald-green mica with nacreous lustre from the Pinzgau.

CHROME-OCHRE. Native chromic oxide.

CHROME-RED and **CHROME-YELLOW.** See CHROMATES OF LEAD (p. 934).

CHROMIC ACID. (pp. 931, 952).—**CHROMITE.** Syn. with CHROME-IRON ORE.

CHROMITES. Compounds of sesquioxide of chromium with protoxides (p. 951).

CHROMIUM. *Symbol* Cr. *Atomic weight* 26·2.—This metal was discovered by Vauquelin in 1797. It is not very abundant, and never occurs in the free state. It is found as sesquioxide (*chrome-ochre*), as sesquioxide combined with protoxide of iron (*chrome-iron ore*), as chromate of lead (*crocoisite* or *red lead-spar*, p. 934); in small quantity in many iron ores, and frequently in meteoric iron; it is also the colouring principle of many minerals, as the emerald, green serpentine, olivin, &c.

The most abundant ore of chromium is chrome-iron. This mineral ignited with alkalis in presence of oxidising agents, yields a chromate of the alkali-metal; these salts treated with acids and reducing agents yield sesquioxide of chromium; and from this substance the metal itself, and many of its compounds, may be prepared.

Metallic chromium is obtained by reduction of the oxides or chlorides, as when sesquioxide of chromium is mixed with one-third of its weight of lamp-black or sugar-charcoal and exposed in a crucible lined with charcoal to the heat of a blast furnace; the metal is thereby obtained as a whitish-grey mass, which cannot be melted together into a button. Péligot, by heating the violet sesquichloride of chromium with potassium, obtained the metal in the form of a dark grey powder. Frémy, by heating the sesquichloride in a porcelain tube and passing vapour of sodium over it in a current of hydrogen, obtained it in very hard shining crystals. Bunsen, by electrolysing a solution of the sesquioxide, obtained the metal in brittle laminæ, having the colour of iron and metallic lustre. According to Berzelius, when sesquichloride of chromium is heated in an atmosphere of hydrogen, there is obtained, besides the protochloride, a shining deposit of metallic chromium.

Wöhler (Ann. Ch. Pharm. cxi. 230) obtains metallic chromium by reducing the sesquichloride with zinc. One pt. of the violet sesquichloride, and 2 pts. of a mixture of the chlorides of potassium and sodium (7 pts. chloride of sodium to 9 pts. chloride of potassium) are closely pressed into an ordinary earthen crucible, 2 pts. of zinc are laid on the mixture, and the whole is covered with a layer of the flux. The crucible is then gradually heated to redness, and the mass is kept in a state of fusion, till a hissing noise is heard, and a zinc-flame is observed on removing the cover for a moment. The crucible is then taken out, gently tapped to cause the metal to collect, and left to cool. A good regulus of zinc is then found at the bottom covered with a green slag. This regulus is well washed with water and digested in dilute nitric acid, which dissolves the zinc, and leaves the chromium in the form of a grey powder, which must be purified by again heating it with nitric acid and washing. By this method Wöhler obtained 6 or 7 grms. of metal from 30 grms. of the chloride, the calculated quantity being 10 grms. Magnesium may be used in the reduction instead of zinc, but it offers no particular advantage. With cadmium as the reducing agent, a violent explosion occurred.

Chromium obtained by Wöhler's process is a light green, glistening, crystalline powder, which, when magnified fifty times, exhibits aggregates of crystals like fir-branches, interspersed with individual crystals of tin-white colour, high lustre, and specific gravity 6·81 according to Wöhler, 7·3 according to Bunsen. These crystals, according to Wöhler, have the form of a very acute rhombohedron; but according to Bolley (Chem. Soc. Qu. J. xiii. 334), who examined them with a magnifying power of 85, they are quadratic octahedrons with acuminated summits and bevelled terminal edges, and very frequently united by fours in the form of a cross. This is the third example known of an elementary body crystallising in the dimetric or quadratic system, the others being tin and boron; as a general rule, ductile metals crystallise in the monometric or regular system; brittle metals in the hexagonal system.

Wöhler's chromium does not exert the slightest action on the magnetic needle. When heated to redness in the air, it acquires a yellow and blue tarnish like steel, and gradually becomes covered with a thin film of green oxide; but the oxidation is by no means complete. Thrown into a spirit flame fed with oxygen, it burns with sparkling, but not so brightly as iron. On melting chlorate of potassium it burns with dazzling white light. Melting nitre oxidises it very readily, but without incandescence. In melting carbonate of sodium it remains unaltered. Heated in chlorine gas, it exhibits vivid incandescence. It is but superficially converted into green oxide by ignition in a stream of aqueous vapour free from air. Hydrochloric acid dissolves it readily, with evolution of hydrogen, forming blue chromous chloride. Dilute sulphuric acid does not act upon it at ordinary temperatures, but on applying a gentle heat, a violent action suddenly takes place, and the remaining metal acquires the power of dissolving easily in the most dilute sulphuric acid, even after washing. It is not attacked by nitric acid, either concentrated or dilute. (Wöhler.)

The properties of chromium differ considerably, according to the manner in which it is prepared, the peculiarity doubtless depending chiefly on the state of aggregation. Péligot's chromium oxidised with great facility, taking fire in the air, even at a heat below redness, and being converted into green sesquioxide. It likewise dissolved in dilute sulphuric and hydrochloric acids, and was oxidised by nitric acid.

The crystals of chromium obtained by Frémy belong, according to Sénarmont, to the regular system. They were not attacked by any acid, not even by nitromuriatic acid.

Chromium may be polished, and then acquires a fine metallic lustre. When pure it is even less fusible than platinum (Deville, Polyt. Centralbl. 1857, p. 605). A fragment of it scratches glass; it is at least as hard as corundum.

Chromium unites with *bromine*, *chlorine*, *fluorine*, *iodine*, *cyanogen*, *nitrogen*, *oxygen*, *phosphorus*, and *sulphur*, also with *aluminium* and *iron*. There are two classes of chromium-compounds, into which the chromium enters as the positive or basic element, namely, the chromous compounds, in which it is monatomic, *e. g.* $CrCl$, Cr^2O, Cr^2SO^4, &c., and the chromic compounds, in which it is sesquiatomic *e. g.* Cr^2Cl^3, Cr^4O^3, $Cr^4(SO^4)^3$, &c. It likewise forms an oxide or anhydride, Cr^2O^3, in which it is triatomic, and to this there corresponds a class of salts, the chromates, into which the chromium likewise enters as a triatomic radicle, *e. g.* chromate of lead, $\left.\begin{matrix}Cr'''\\Pb\end{matrix}\right\}O^2$.

CHROMIUM, BROMIDES OF. The *anhydrous sesquibromide*, Cr^2Br^3, may be prepared, like the chloride, by passing bromine-vapour over an ignited mixture of chromic oxide with charcoal and starch-paste. Part of the resulting bromide then sublimes beyond the mass of oxide, while another portion remains therein in crystalline scales, which, however, are easy to separate. It forms black semi-metallic hexagonal scales, translucent with olive-green colour, and exhibiting in one direction a faint red dichroism. It forms a yellowish-green powder when triturated, in which form also part of the compound sublimes during the preparation. It is quite insoluble when pure, but dissolves to a green liquid if mixed with protobromide. It is decomposed by alkalis more easily than the chloride. When gently heated in hydrogen gas, it is reduced to the white protobromide, $CrBr$, which on exposure to the air quickly deliquesces to green oxybromide. (Wöhler, Ann. Ch. Pharm. lxi. 382.)

A solution of chromic bromide is obtained by dissolving chromic hydrate in hydrobromic acid, or by treating chromate of silver with hydrobromic acid and alcohol. The solution yields green crystals, and is easily decomposed by evaporation, with formation of oxybromide.

CHROMIUM, CHLORIDES OF. Two chlorides of chromium are known in the free state, viz. $CrCl$ and Cr^2Cl^3. A trichloride, $CrCl^3$, may also be supposed to exist, combined with chromic anhydride, in chlorochromic anhydride, $CrCl^3.Cr^2O^3$.

Protochloride of Chromium or Chromous Chloride. $CrCl$. (Moberg, J. pr. Chem. xxix. 175; Péligot, Ann. Ch. Phys. [3] xii. 527.)—This compound is obtained by passing hydrogen gas over perfectly anhydrous sesquichloride of chromium very gently heated, as long as hydrochloric acid gas continues to escape. The hydrogen must be previously freed from all traces of oxygen by passing it through a solution of protochloride of tin in caustic potash, then through tubes containing sulphuric acid and chloride of calcium, and lastly over red-hot metallic copper. The protochloride is also formed by passing dry chlorine gas over a red-hot mixture of charcoal and chromic oxide. The first method yields the protochloride in the form of a white, velvety substance, retaining the form of the sesquichloride from which it has been formed; the second method yields it in fine white crystals, usually mixed, however, with chromic oxide, chromic chloride, and charcoal.

Protochloride of chromium dissolves in water, with evolution of heat, forming a blue solution, which rapidly turns green when exposed to the air or to chlorine gas. With *potash* it forms a dark brown precipitate (yellow, according to Moberg, if the air be completely excluded) of hydrated chromous oxide, which, however, quickly changes to light brown chromosochromic oxide, with evolution of hydrogen. *Ammonia* forms a sky-blue precipitate, which turns green on exposure to the air. With ammonia and sal-ammoniac, a blue liquid is formed, which turns red on exposure to the air. *Sulphide* *of ammonium* or *potassium* forms a black precipitate of chromous sulphide. The solution of protochloride of chromium is one of the most powerful deoxidising agents known. With a solution of *neutral chromate of potassium*, it forms a dark brown precipitate of chromosochromic oxide, which, however, disappears on the addition of an excess of the protochloride, and forms a green solution. It precipitates *calomel* from a solution of corrosive sublimate. With *cupric salts*, it forms at first a white precipitate of cuprous chloride, but when added in excess, throws down red cuprous oxide. It instantly converts *tungstic acid* into blue oxide of tungsten, and precipitates *gold* from the solution of the chloride.

A solution of chromous chloride containing zinc, may be obtained, according to Loewel (J. pr. Chem. lxii. 11), by pouring a solution of the sesquichloride, or of chrome-alum, in 3 to 5 pts. water, made as neutral as possible, into a bottle nearly filled with granulated zinc. Hydrogen is then evolved for some hours, and a fine blue liquid is formed, which, if left to stand in contact with the zinc, continues slowly to evolve hydrogen and deposit a light grey chromous oxychloride, and after four or six months becomes perfectly colourless.

SESQUICHLORIDE OF CHROMIUM. Chromic Chloride. Cr^2Cl^3.—The anhydrous sesquichloride is prepared by igniting an intimate mixture of chromic oxide and charcoal in a stream of dry chlorine gas. A mixture of the oxide with lamp-black is made up into pellets with starch; these are well baked in a covered crucible, and then introduced into another crucible, through the bottom of which there passes a porcelain tube connected with an apparatus for evolving chlorine. Into the mouth of this crucible is fitted a smaller one, placed in an inverted position. The lower crucible stands on the grate of an ordinary air-furnace, and, as soon as the apparatus is filled with dry chlorine, the mixture is heated to bright redness, the firing being so regulated as to keep the upper crucible comparatively cool, so that the chloride as it is produced may sublime into it. When the process is completed, the stream of chlorine must be kept up till the apparatus is cool, to prevent the formation of sesquioxide or protochloride. The sesquichloride is then washed with water to free it from chloride of aluminium derived from the crucible. If it contains protochloride, which is the case if the stream of chlorine has not been strong enough, it will dissolve during washing (Wöhler, Pogg. Ann. xi. 148). The sesquichloride may also be obtained by heating the sesquisulphide in a stream of dry chlorine. (Berzelius.)

Anhydrous chromic chloride forms shining micaceous laminæ of a beautiful peach-blossom colour, which may be rubbed on the skin like talc. It is quite insoluble in cold water; but, if boiled in the finely divided state with water, it slowly dissolves and forms a green solution. If the cold water contains in solution a small quantity of chromous chloride, not even exceeding $\frac{1}{4000}$ to $\frac{1}{1000}$, the sesquichloride dissolves immediately, with evolution of heat, forming a green solution identical with that obtained by dissolving chromic hydrate in hydrochloric acid. This effect is perhaps due to the formation of an intermediate chloride, which is immediately resolved by the action of water into protochloride and the soluble green modification of the sesquichloride, the protochloride thus liberated again acting in the same manner (see p. 943). The addition of a small quantity of stannous or cuprous chloride is said to produce the same effect.

Anhydrous chromic chloride is not decomposed by sulphuric acid, either strong or dilute, or by hydrochloric, nitric, or nitromuriatic acid, or by ammonia, carbonate of potassium, or carbonate of sodium: *caustic potash* attacks it but slightly at the boiling heat. Fused with *nitre* and an *alkali* or *alkaline carbonate*, it yields a chromate and chloride of the alkali-metal. *Potassium, zinc*, &c., separate metallic chromium from it. Heated in a stream of *hydrogen*, it yields chromous chloride, and if the heat be strong, metallic chromium is likewise separated. Heated to redness in the *air*, it gives off chlorine and yields green chromic oxide. By ignition in *phosphoretted hydrogen gas*, it is converted into phosphide of chromium. Heated with *sulphur*, or in a stream of *sulphydric acid gas*, it yields sulphide of chromium. Ignited in *ammonia gas*, it forms nitride of chromium.

By dissolving chromic oxide in hydrochloric acid, or by boiling chromate of lead or silver with hydrochloric acid and alcohol, or even with excess of hydrochloric acid alone, a green solution is obtained, containing the modification of chromic chloride which corresponds to the green chromic oxy-salts (p. 950). This solution, when evaporated, yields a non-crystalline dark green syrup, which, when heated to 100° C. in a stream of dry air, yields a green mass containing $2Cr^2Cl^3.9H^2O$ (Moberg, J. pr. Chem. xxix. 175). The same solution evaporated in vacuo yields green granular crystals containing $Cr^2Cl^3.H^2O$. (Péligot, *ibid.* xxxvii. 475.)

Hydrated chromic chloride heated to 250° C. in a stream of hydrochloric acid or chlorine gas, gives off its water and yields delicate peachblossom-coloured scales, which are soluble in water and even deliquescent; but, if more strongly heated in either of these gases, it begins to sublime, and the sublimed chloride thus obtained is insoluble in water, like that obtained by igniting chromic oxide with charcoal in a stream of chlorine. The anhydrous chloride cannot be obtained by heating the hydrated chloride in the air: for hydrochloric acid is then given off and soluble oxychloride produced, afterwards an insoluble oxychloride, and the residue ultimately consists of green chromic oxide. In this respect, the hydrated sesquichloride of chromium resembles the corresponding compounds of iron and aluminium.

Nitrate of silver added to a green solution of chromic chloride, throws down at first only $\frac{1}{3}$ of the chlorine; but on leaving the liquid to stand, or on boiling it, the whole of the chlorine is precipitated. This effect was attributed by Berzelius to the tendency of chromic chloride to form double salts; by Otto to the solubility of chloride of silver in chromic nitrate.

A solution of chromic chloride, corresponding to the violet solutions of the chromic salts of oxygen-acids, may be obtained by precipitating one of these violet salts by an alkali, and dissolving the precipitated hydrate in hydrochloric acid; also by decomposing the violet sulphate with chloride of barium. From these solutions nitrate of silver immediately throws down all the chlorine. If, however, the violet solution of the chloride be boiled, it turns green, and after this change the chlorine is but partially precipitated by nitrate of silver.

Chromic chloride unites with the chlorides of the more basic metals, forming salts containing $MCl.Cr^2Cl^3$, or MCr^2Cl^4, of which however only the potassium, sodium, and ammonium-compounds have been investigated. They are obtained by mixing the corresponding acid chromates with excess of hydrochloric acid and alcohol, and evaporating over the water-bath till the mass turns violet. The double chlorides thus obtained become green and deliquesce on exposure to the air. Treated with a small quantity of cold water, they dissolve, with deep yellowish-red colour, which in a short time passes into pure chrome-green. If the solution be then left to evaporate, the alkaline chloride separates out, and the chromic chloride remains in the form of a green syrup. These double chlorides belong therefore to the violet modifications of chromic salts, but are decomposed by water into chloride of alkali-metal and green chromic chloride, which does not form double chlorides. The effect of chromous, stannous, and cuprous chlorides in facilitating the solution of anhydrous chromic chloride in water (p. 942) probably depends upon the formation of analogous double chlorides. If the double chloride decomposed by slow evaporation be mixed with hydrochloric acid and evaporated to dryness over the water-bath, the double chloride is reproduced. When the dry double chlorides are treated with absolute alcohol, green chromic chloride dissolves, and a rose-coloured salt remains, consisting, according to Berzelius, of $3MCl.Cr^2Cl^3$.

CHROMIUM, DETECTION AND ESTIMATION OF. 1. All compounds of chromium ignited with a mixture of *nitre* and an *alkaline carbonate* yield a chromate of the alkali-metal, which may be dissolved out by water, and on being neutralised with acetic acid, will give the characteristic precipitates of chromic acid with lead and silver-salts.

The oxides of chromium and their salts, fused with *borax* in either blowpipe flame, yield an emerald-green glass. The same character is exhibited by those salts of chromic acid whose bases do not of themselves impart decided colours to the bead. The production of the green bead in both flames distinguishes chromium from uranium and vanadium, which give green beads in the inner flame only.

2. *Reactions in Solution.*—The sesqui-salts of chromium or chromic salts exhibit two principal modifications, the green and the violet. *Ammonia* produces in solutions of the green salts, a greyish-green precipitate; in solutions of the violet salts, a greyish-blue precipitate, both of which however yield green solutions with sulphuric or hydrochloric acid. The liquid above the precipitate has a reddish colour, and contains a small quantity of chromic acid. *Potash* and *soda* form similar precipitates, which dissolve in excess of the alkali, forming green solutions from which the chromic oxide is precipitated by boiling. The *alkaline carbonates* form greenish precipitates (violet by candle-light) which dissolve to a considerable extent in excess of the reagent. *Sulphydric acid* forms no precipitate; *sulphide of ammonium* throws down the hydrated sesquioxide.

Zinc, immersed in a solution of chrome-alum or sesquichloride of chromium, excluded from the air, gradually reduces the chromic salt to a chromous salt, the liquid after a few hours acquiring a fine blue colour, and hydrogen being evolved by decomposition of water. If the zinc be left in the liquid after the change of colour from green to blue is complete, hydrogen continues to escape slowly, and the liquid, after some weeks or months, is found no longer to contain chromium, the whole of that metal being precipitated in the form of a basic salt, and its place taken by zinc. *Tin*, at a boiling heat, likewise reduces the chromic salt to a chromous salt, but only to a limited extent;

and on leaving the liquid to cool after the action has ceased, a contrary action takes place, the protochloride of chromium decomposing the protochloride of tin previously formed, reducing the tin to the metallic state, and being itself reconverted into sesquichloride. *Iron* does not reduce chromic salts to chromous salts, but merely precipitates a basic sulphate of chromic oxide, or an oxychloride, as the case may be.

Chromous salts are but rarely met with in solution: for their characters, see Protochloride of Chromium (p. 942).

Chromic acid and its salts are recognised in solution by forming a pale yellow precipitate with *barium*-salts, bright yellow with *lead*-salts, brick red with *mercurous*-salts, and crimson with *silver*-salts (p. 932).

3. *Quantitative Estimation.*—Chromium is usually estimated in the state of sesquioxide. When it exists in solution as a sesqui-salt, it may be precipitated by ammonia, care being taken to avoid a large excess of that reagent (which would dissolve a portion), and to heat the liquid for some time. The chromic oxide is then completely precipitated, and the precipitate, after washing and drying, is reduced by ignition to the state of anhydrous sesquioxide, containing 69·1 per cent. of the metal.

When chromium exists in solution in the state of chromic acid, it is best to precipitate it by a solution of mercurous nitrate; the mercurous chromate thereby thrown down yields by ignition the anhydrous sesquioxide. The chromic acid might also be precipitated and estimated in the form of a barium or lead-salt.

Chromic acid may also be estimated by means of oxalic acid, which reduces it to sesquioxide, being itself converted into carbonic acid. The quantity of carbonic anhydride evolved determines the quantity of anhydrous chromic acid present, 3 at. CO^2 corresponding to 1 at. Cr^2O^3, as shown by the equation:

$$2Cr^2O^3 + 3C^2H^2O^4 = Cr^4O^3 + 6CO^2 + 3H^2O.$$

The mixture may be heated in the carbonic acid flask represented in *fig.* 5, p. 119. If the object be merely to determine the quantity of chromium present, any salt of oxalic acid may be used; but if the alkalis are also to be estimated in the remaining liquid, the ammonium or barium-salt must be used.

Lastly, chromic acid may be estimated by Bunsen's volumetric method. The chromic acid is decomposed by boiling with excess of hydrochloric acid, whereupon 1 at. chromic anhydride eliminates 3 at. chlorine:

$$Cr^2O^3 + 6HCl = Cr^2Cl^3 + 3H^2O + Cl^3;$$

and the 3 at. chlorine passed into a solution of iodide of potassium, liberate 3 at. iodine, which is estimated by a standard solution of sulphurous acid, as described under Volumetric Analysis (p. 264), so that 3 at. iodine correspond to 1 at. Cr^2O^3.

4. *Separation of Chromium from other Elements.*—Chromic oxide, in the state of neutral or acid solution, is easily separated from the *alkalis* or *alkaline earths* by precipitation with ammonia, care being taken in the latter case to protect the liquid and precipitate from the air. The same method, with addition of sal-ammoniac, serves to separate chromic oxide from *magnesia*. The separation from the alkaline earths and from magnesia may also be effected by precipitating the whole with an alkaline carbonate, and igniting the precipitate with a mixture of carbonate of sodium and nitre. The chromium is then converted into chromate of sodium, which may be dissolved out, and the solution, after neutralisation with nitric or acetic acid, treated with mercurous nitrate as above.

From *alumina* and *glucina*, chromic oxide may be separated by treating the solution with excess of potash, and boiling the liquid to precipitate the chromic oxide. The separation is, however, more completely effected by fusing with nitre and carbonate of sodium, treating the fused mass with water, adding an excess of nitric acid to dissolve anything that may be insoluble in water, and precipitating the alumina or glucina by ammonia.

Another method of converting chromic oxide into chromic acid, and thereby effecting its separation from the above-mentioned oxides, is to treat the mixture with excess of potash, and heat the solution gently with peroxide of lead. The whole of the chromium is then converted into chromic acid, and remains dissolved as chromate of lead in the alkaline liquid; and on filtering from the excess of peroxide of lead, and any other insoluble matter that may be present, and supersaturating the filtrate with acetic acid, the chromate of lead is precipitated. (Chancel, Compt. rend. xliii. 927.)

Chromic acid may be separated from the *alkalis* in neutral solutions by precipitation with mercurous nitrate; also by reducing it to chromic oxide with hydrochloric acid and alcohol, and precipitating by ammonia. From the *earths* it may also be separated by this latter method, or, again, by fusing with carbonate of sodium, dissolving out with water, &c.

From *iron*, *zinc*, *nickel*, *cobalt*, *uranium*, and *cerium*, chromium may be separated by fusion with nitre and carbonate of sodium, or with the carbonate alone if it is already in the form of chromic acid. Or, again, the separation may be effected by means of potash and peroxide of lead, according to Chancel's method above described.

The separation of chromium from *manganese* cannot be effected immediately in this manner, because the manganese is at the same time converted into manganate or permanganate of sodium; but on dissolving in water and adding alcohol to the solution, the manganese is reduced to peroxide and completely precipitated, while the chromium remains dissolved as chromate.

From *titanium*, *tantalum*, and *columbium*, chromium, if in the state of sesquioxide, may be separated by fusing the mixture with nitre and alkaline carbonate, extracting with water, reducing the chromium to the state of sesquioxide by boiling with hydrochloric acid, and precipitating by ammonia.

From *copper*, *lead*, *tin*, and the other metals of the first group (p. 217), chromium is separated by sulphydric acid.

To estimate chromic acid in presence of *sulphuric acid*, the chromium is first reduced to sesquioxide as above; the sulphuric acid is then precipitated, after considerable dilution, by chloride of barium; the excess of barium is removed by sulphuric acid: and the chromic oxide precipitated by ammonia.

When *phosphoric acid* is present in solution, together with chromic acid, the phosphoric acid is precipitated as phosphate of magnesium and ammonium, and then the chromic acid by any of the preceding methods.

Hydrochloric acid is separated from chromic acid by nitrate of silver, and the excess of silver is removed by sulphuretted hydrogen, the chromic acid being at the same time reduced to sesquioxide, which may be precipitated by ammonia.

Silicic acid is separated from chromic acid in the same manner as from all other substances, and the chromium is afterwards precipitated as oxide.

When sesquioxide of chromium and chromic acid occur together in solution, the chromic acid may be precipitated by mercurous nitrate, the solution being first completely neutralised, and the sesquioxide precipitated from the filtrate by ammonia, which at the same time throws down a mercury-compound, to be afterwards separated from the chromic acid by ignition.

Valuation of Chrome-ores.—The value of a chrome-ore depends upon the quantity of chromic acid that it will yield. To ascertain this point, the ore is calcined with a mixture of nitre, alkali, and lime, the use of the lime being to keep the mixture in a pasty condition, and prevent the heavy ore from falling to the bottom (see p. 936), after which the soluble chromate is extracted, and the amount of chromic acid may then be determined by any of the methods already given.

Professor Calvert of Manchester, has given two processes for the valuation of chrome ores. (Chem. Soc. Qu. J. v. 194.)

a. The ore in fine powder is mixed with three or four times its weight of soda-lime (obtained by slaking quick lime with caustic soda, then drying and calcining the mass), and to this mixture of soda-lime and ore is added one-fourth of nitrate of sodium. The whole is then well calcined for two hours, care being taken to stir the pasty mass every quarter of an hour with a platinum wire. This mixture not becoming fluid, the ore is constantly kept in contact with the oxygen of the atmosphere, and thus the oxide of chromium is converted into chromic acid. One treatment is generally sufficient for the complete decomposition of the ore.

The greater part of the mass is now dissolved in water, and the insoluble portion treated with sulphuric acid diluted with twice its bulk of water; the whole is then removed from the crucible, and a little alcohol is added to the solution in order to render the sulphate of calcium insoluble. The whole is next thrown on a filter and washed with weak alcohol, which dissolves all the acid chromate formed, and leaves the sulphate of calcium, together with any portion of ore that may not have been attacked. The sulphate of calcium may be removed by washing the filter with boiling water, and the residual ore, if any, is to be recalcined.

The solution containing the acid chromate of sodium is now neutralised with ammonia, and oxalate of ammonium is added, which gives rise to a small precipitate of sesquioxide of iron, alumina, and oxalate of calcium, together with a little silica dissolved by the sulphuric acid. The precipitate having been separated and well washed, the liquor is either mixed with alcohol to reduce the chromic acid to the state of sesquioxide, which may then be precipitated, washed, dried, ignited, and weighed; or, better, the liquor is rendered acid, and the amount of chromic acid estimated by Penny's process (Chem. Soc. Qu. J. iv. 239) with dichloride* of tin (commonly called *protochloride*). This method depends on the reaction of dichloride of tin with acid chromate of sodium or potassium in presence of free hydrochloric acid, whereby

---

* Atomic weight of tin = 118.

the dichloride of tin is converted into tetrachloride, and the chromic acid into sesquichloride of chromium:

$$3SnCl^2 + 2NaCrO^2.Cr^2O^3 + 14HCl = 3SnCl^4 + 2NaCl + 7H^2O + 2Cr^2Cl^6.$$

A solution of dichloride of tin of known strength* is added to the solution of acid chromate of sodium, till the latter is completely decomposed,—which may be known by the solution no longer giving a yellow precipitate with acetate of lead—and the quantity of acid chromate present is calculated from the amount of tin in the solution used. Penny has shown, by direct experiment, that in the above reaction, 100 pts. of metallic tin correspond to 83·2 pts. of acid chromate of potassium, or 78·4 pts. of acid chromate of sodium.

b. The finely divided ore is calcined with nitrate of barium, a small quantity of caustic potash being added towards the end of the operation to facilitate the action, and give rise to chromate of potassium. The pasty condition of the fused baryta prevents the ore from falling to the bottom, and thus keeps it in contact with the air. On cooling, the crucible and its contents are immersed in dilute nitric acid, which dissolves the greater portion of the mass, leaving the unattacked ore, which, after being washed, may be recalcined. The liquor containing the acid chromates of potassium and barium, nitrate of barium, sesquioxide of iron, alumina, and lime, is first heated with sulphate of potassium, which throws down the baryta as sulphate, which is collected on a filter and washed; ammonia and oxalate of ammonium are then added to throw down sesquioxide of iron, alumina, and lime; the mixed precipitate is collected and washed; and the amount of chromic acid determined as before.

5. *Atomic Weight of Chromium.*—Berzelius, in 1818 (Schw. J. xxii. 53), estimated the atomic weight of chromium from the composition of chromate of lead. 100 pts. nitrate of lead (containing 67·31 Pb^2O), yielded by precipitation with chromate of potassium, 98·772 pts. $Pb^2O.Cr^2O^3$; whence, taking the atomic weight of lead at 103·59, that of chromium was found to be 28·14.

Péligot, in 1844 (Ann. Ch. Phys. [3] xii. 528), showed that this number was too high. From the analysis of chromous chloride, CrCl, in which he found 56·7 to 58·4 per cent. chlorine, and likewise from that of the acetate, he estimated the atomic weight of chromium at 26·24.

Berlin (Ann. Ch. Pharm. lvi. 207; lx. 182), analysed chromate of silver by precipitating the silver with hydrochloric acid, then reducing the chromic acid in the filtrate to chromic oxide, and precipitating by ammonia. From the quantity of chloride of silver obtained (Ag = 108; Cl = 35·206), he found, as a mean of five experiments, Cr = 26·34, and by comparing the quantity of chromic oxide precipitated with the original quantity of chromate of silver, Cr = 26·27.

Berlin likewise adopted the method of Berzelius, and found that 100 pts. nitrate of lead yield from 97·559 to 97·594 pts. chromate of lead, whence, as a mean result, Cr = 25·99.

Moberg, in 1841 (J. pr. Chem. xliii. 114; xliv. 322), estimated the atomic weight of chromium by the analysis of chromic sulphate and of ammoniacal chrome-alum. From the quantity of chromic oxide in the sulphate dried at 300° C. he found Cr = 26·55; from that which remained after heating ammonio-chrome-alum to bright redness, Cr = 26·78.

Lefort, in 1850 (J. Pharm. [3] xviii. 27), determined the quantity of baryta in chromate of barium, by dissolving the salt in nitric acid and precipitating by sulphuric acid. In fourteen experiments, he found that 100 pts. chromate of barium yielded 60·35 to 60·01 baryta; mean 60·19: whence, if Ba = 68·56, Cr = 26·64.

Lastly, **Wildenstein**, in 1853 (J. pr. Chem. lix. 27), determined the quantity of chromate of barium precipitated from chloride of barium by neutral chromate of potassium. As a mean of 32 experiments, he found that 100 pts. chromate of barium correspond to 81·70 of the chloride; the limits were 81·52 and 81·86. If then Ba = 68·56 and Cl = 35·46, the value of Cr is 26·76

As the precipitation of baryta by sulphuric acid is affected by an error arising from the carrying down of a portion of the dissolved salt with the precipitated sulphate, and as moreover the atomic weight of barium is not very exactly known, it is probable that the determinations of the atomic weight of chromium by Berlin and by Péligot, are the most exact, and the number 26·24 may be considered very near to the true value. (Handw. d. Chem. 2te Aufl. ii. [1] 482.)

CHROMIUM, FLUORIDES OF. The *sesquifluoride*, Cr^2F^6, is obtained by treating the sesquioxide, dried, but not ignited, with excess of hydrofluoric acid, and heating the dried mass very strongly in a platinum crucible. It is dark green, melts at a high temperature, and is but very slightly volatile, even at the melting point of steel. When subjected to the highest temperature produced by a lamp urged

---

* The strength of a solution of dichloride of tin is most easily ascertained by means of a standard solution of pure acid chromate of potassium.

by bellows, it sublimes in shining regular octahedrons (Deville, Ann. Ch. Pharm. cl. 197). Berzelius obtained it as a green crystalline saline mass.

Chromic fluoride unites with the fluorides of ammonium, potassium, and sodium, forming green sparingly soluble compounds.

Trifluoride, CrF^3.—This compound, discovered by Unverdorben, is obtained by distilling 1 pt. of chromate of lead with 1 pt. fluor spar and 3 pts. fuming oil of vitriol in a leaden retort, and collecting the vapours in a perfectly dry leaden receiver kept at a very low temperature: it then condenses to a blood-red, strongly fuming liquid, which becomes gaseous again at a temperature very little higher. The vapour is red, and when inhaled, produces violent coughing and severe oppression of the lungs. It is decomposed by water, forming hydrofluoric and chromic acids, and when it mixes with the air, forms a thick white fume, coloured orange-yellow on the edges by minute particles of chromic acid. With ammonia it unites, according to Unverdorben, forming a yellow volatile body; but, according to Berzelius, it is decomposed with slight explosion, producing nitrogen gas, water, and hydrofluoric acid. Metals and other reducing agents, organic as well as inorganic, abstract part of the fluorine, leaving the sesquifluoride. Silicic acid decomposes it immediately, forming fluoride of silicium and chromic acid; hence it corrodes glass; it may be kept, however, for a while in glass vessels coated with resin.

H. Rose (Pogg. Ann. xxvii. 565), supposed that the formula of this compound was CrF^5, because it contains more fluorine than the formula CrF^3 requires, and its decomposition by water is attended with evolution of oxygen, as well as the formation of chromic and hydrofluoric acids. Berzelius, on the contrary, was of opinion that the excess of fluorine above 3 atoms arose from admixture of hydrofluoric acid, and that the evolution of oxygen in its decomposition by water, was due to the previous mixture of that gas with the vapour of the fluoride, inasmuch as the residue obtained in the preparation of the compound always contains chromic oxide.

A fluoride of intermediate composition between the sesqui- and tri-fluorides is obtained in solution by dissolving brown oxide of chromium in hydrofluoric acid. The solution is red, and yields by evaporation a rose-coloured salt, which is redissolved without alteration by water, and precipitated brown by ammonia.

CHROMIUM, IODIDES OF. The *sesqui-iodide*, Cr^2I^3, is obtained in solution by dissolving chromic hydrate in hydriodic acid, or by treating chromate of silver with hydriodic acid and alcohol. It is green, and yields by evaporation a green glassy residue, which splits into small pieces on cooling. It is insoluble in cold, easily soluble in warm water, but does not separate out again on cooling. No other iodide of chromium is known with certainty.

CHROMIUM, NITRIDE OF. Cr^3N^2? This compound is produced when sesquichloride of chromium is heated in a stream of ammonia-gas: probably thus:

$$3Cr^2Cl^3 + 13NH^3 = 2Cr^3N^2 + 9NH^4Cl + H^3;$$

also when chlorochromic anhydride is treated in a similar manner. It is a brown powder, which, when heated to 150°—200° C. in a stream of oxygen, takes fire and burns with a red light, giving off nitrogen gas and a small quantity of pernitric oxide, and leaving sesquichloride of chromium. (Liebig, Pogg. Ann. xxi. 359.—Schrötter, Ann. Ch. Pharm. xxxvii. 148.—Gm. iv. 139.)

CHROMIUM, OXIDES OF. Chromium forms several compounds with oxygen, namely, the *protoxide*, Cr^2O, the *sesquioxide*, Cr^4O^3, the *trioxide*, or *chromic anhydride*, Cr^2O^3; also an oxide, Cr^3O^2, intermediate between Cr^2O and Cr^4O^3, and several oxides intermediate between Cr^4O^3 and Cr^2O^3.

PROTOXIDE OF CHROMIUM. CHROMOUS OXIDE, Cr^2O. (Moberg, J. pr. Chem. xliv. 322.—Péligot, Ann. Ph. Phys. [3] xii. 528.)—This oxide probably exists in some specimens of chrome-iron ore (p. 939) and in pyrope. It is precipitated as a hydrate by the action of potash on a solution of the protochloride. The anhydrous protoxide has not been obtained. The hydrate, $2Cr^2O.H^2O$, is very unstable, decomposes water even at ordinary temperatures, and unless carefully protected from the air, by precipitating with a well-boiled solution of potash, is converted, as soon as it is formed, into chromoso-chromic oxide, with evolution of hydrogen. It must be dried in an atmosphere of hydrogen. It is yellow when recently precipitated, brown when dry, and may be preserved unaltered in dry air. When ignited, it gives off hydrogen and leaves sesquioxide: $2Cr^2O.H^2O = Cr^4O^3 + H^2$.

Chromous hydrate is insoluble in dilute acids, but dissolves slowly in strong acids. The chromous salts are most easily prepared by mixing a solution of the protochloride with the potassium or sodium-salt of the corresponding acid. They are generally of a red colour, sometimes inclining to blue, dissolve but sparingly in cold water, more readily in hot water. Like ferrous salts, they dissolve large quantities of nitric oxide, forming dark brown solutions. (For their other reactions, see PROTOCHLORIDE OF CHROMIUM, p. 942.)

CHROMOSO-CHROMIC OXIDE, Cr^3O^2, or $Cr^2O.Cr^4O^3$.—Formed when protochloride of chromium is precipitated by potash without the precautions above mentioned for excluding the air. After washing in water and drying in the air, it has the colour of Spanish tobacco. It is but slightly attacked by acids.

SESQUIOXIDE OF CHROMIUM. CHROMIC OXIDE, Cr^4O^3.—This oxide exists in chrome-iron ore (p. 939), and in chrome-ochre. The latter occurs as a yellowish-green, earthy or argillaceous deposit generally mixed with clay, in the Shetland Isles, at Creuzot in France, at Halle and Waldenburg in Silesia, at Martenberg in Sweden, &c. (Dana, ii. 339). It is produced by heating chromium to redness in the air, by the ignition of chromic hydrate, by the decomposition of chromic anhydride and of various chromates, some of these processes yielding it in the amorphous, others in the crystalline state.

a. Amorphous. 1. When mercurous chromate is heated as long as oxygen and vapour of mercury are evolved, chromic oxide remains of a very fine green colour. It is best to heat the salt in a covered crucible, since, if the air has free access to it, part of the sesquioxide is converted into brown oxide, which impairs its colour. (Otto.) —2. When acid chromate of potassium is heated to redness with sulphur, the chromic acid is reduced, sulphurous anhydride is evolved, and there remains a mixture of chromic oxide with sulphide and sulphate of potassium, from which the soluble salts may be extracted by water. (Lassaigne, Ann. Ch. Phys. [3] xiv. 299.)—3. Berthier ignites chromate of potassium in a charcoal crucible, or mixes it with charcoal powder or lamp-black, and ignites it in an ordinary earthen crucible; dissolves the chromite of potassium produced in cold water; heats the filtrate to the boiling point; collects the precipitated hydrate on a filter; washes it thoroughly with water; and lastly ignites it. —4. Wöhler (Pogg. Ann. x. 46) ignites a mixture of acid chromate of potassium with about its own weight of sal-ammoniac and a small quantity of carbonate of sodium in a covered crucible, till no more vapour of sal-ammoniac is disengaged; and then purifies the sesquioxide of chromium from chlorides of potassium and sodium, by washing with water.—5. Barian (Rev. scient. xx. 425) mixes 4 pts. of acid chromate of potassium with 1 pt. of starch; ignites the mixture in a crucible; washes away the resulting carbonate of potassium with water; and again ignites the residue. He states that the chromic oxide thus obtained is so pure that it may be used for glazing porcelain.—6. When acid chromate of ammonium is heated in a platinum or porcelain basin over a lamp, a very energetic action takes place, accompanied by strong incandescence, and green bulky masses of chromic oxide shoot out in every direction, very much resembling unopened tea-leaves. (Böttger, Ann. Ch. Pharm. xlvii. 332.) —7. A very fine and intimate mixture is made of 48 pts. of gunpowder, 240 pts. of perfectly dry acid chromate of potassium, and 5 pts. of equally dry chloride of ammonium. This mixture is made into the shape of a cone (by pressing it into a wine glass, and afterwards carefully shaking it out) and then transferred to an iron plate. A burning fusee or other combustible is then applied to the top of the cone, whereupon it takes fire, and slowly burns throughout its whole mass. On exhausting the cone, while still hot, with water, a residue of chromic oxide is obtained in the form of a pale green powder. (Böttger, *loc. cit.*)

b. Crystallised. 1. When vapour of chloro-chromic anhydride is slowly passed through a glass tube heated to low redness, chlorine and oxygen are evolved, and chromic oxide remains in the tube as a crystalline deposit, sometimes interspersed with larger crystals (Wöhler, Ann. Ch. Pharm. lx. 203).—2. When acid chromate of potassium is heated to whiteness for eighteen hours, a mixture of the neutral chromate and chromic oxide is obtained; and on dissolving out the former with water, chromic oxide remains in fine iridescent spangles (Gentele, J. p. Chem. liv. 184).—3. When dry chlorine is passed over chromate of potassium heated to redness in a porcelain tube, the gas is completely absorbed, oxygen is evolved, and chloride of potassium is formed, together with chromic oxide, in long, shining, green, brittle tablets, if the tube is heated only to a dull redness, but in hard brown crystals like those obtained by Wöhler's method, if the temperature is raised to bright redness (Frémy, Ann. Ch. Pharm. xlix. 274). Blake (*ibid.* cii. 331) found chromic oxide crystallised in plates having the metallic lustre and belonging to the hexagonal system, in the cracks of a furnace which had been used for a long time for the preparation of chromate of potassium from chrome-iron ore.

Crystallised chromic oxide prepared by Wöhler's method forms crystals of rhombohedral character, greenish-black with metallic lustre, and as hard as corundum, so that they scratch glass. Their specific gravity is 5·21, and they yield a greenish powder by trituration.

Amorphous chromic oxide obtained by decomposing the hydrate at a temperature below redness, has a dark green colour; that which has been strongly ignited (methods

1 to 7 p. 948) is bright green. When the oxide prepared at a moderate heat is gradually raised to a higher temperature, it suddenly becomes incandescent and is afterwards nearly insoluble in acids. According to Berzelius, it then contains the indifferent modification of chromium (p. 941). By ignition with nitrate or acid sulphate of potassium, it may be brought back to the soluble state.

Amorphous chromic oxide melts at the heat of a forge-fire, and on cooling forms a greenish-black crystalline mass, exhibiting all the properties of the crystalline oxide obtained by Wöhler's method. It is not reduced by hydrogen gas. Charcoal reduces it at an intense white heat, but only at the points where it is in contact with the charcoal.

Chromic oxide is used in the preparation of green glass and enamel, but especially in the painting of porcelain. It is also used in ordinary painting, forming one of the most permanent greens, called chrome-green.

Hydrated Chromic Oxide. Chromic Hydrates.—Chromic oxide forms several hydrates differing in their properties. When a solution of a green or violet chromic salt is mixed with potash or soda, a bluish-green hydrate is precipitated, which dissolves with emerald-green colour in excess of the precipitant, but is reprecipitated completely as green hydrate on boiling. With ammonia, the violet salts give a grey-blue, the green salts a grey-green precipitate. Both these precipitates dissolve in cold acids, the former with red, the latter with green colour. In excess of ammonia, they both dissolve slowly with peach-blossom colour, the greyish-blue precipitate, however, the more abundantly of the two.

The properties of the hydrates, precipitated by ammonia, are affected to a considerable extent by the concentration and temperature of the chromic solution and of the ammonia, by the way in which they are mixed, &c.; and the results obtained by different experimenters regarding the constitution and properties of these hydrates are by no means accordant. L. Schaffner (Ann. Ch. Pharm. li. 168) describes three modifications of chromic hydrate: the first obtained by boiling chromic chloride with excess of potash, and containing, according to Ordway (Sill. Am. J. [2] xxvi. 197), $Cr^4O^3.4H^2O$, or $H^8Cr^4O^7$; the second, by treating the chloride with sufficient potash to redissolve the precipitate first formed, and neutralising the excess of alkali with hydrochloric acid; the third, by precipitating a solution of a chromic salt with excess of ammonia: the dried precipitate thus obtained is, according to Schaffner, $Cr^4O^3.6H^2O$, or $H^{12}Cr^4O^9$.

The following results have been obtained by Lefort (J. Pharm. [3] xviii. 27). When a chromic salt is treated with excess of caustic soda-solution, the precipitate first formed redissolves with green colour if the original chromic salt was green or red, with bluish-violet colour if the chromic salt was bluish-violet. The solutions, if heated, deposit a gelatinous hydrate of fine green colour, containing $Cr^4O^3.5H^2O$, or $H^5Cr^2O^4$. It becomes hard and black when dry, and yields a dark green powder. The same hydrate is obtained by pouring a chromic salt of either modification into excess of the boiling alkali-solution.

Another green hydrate, $Cr^4O^3.6H^2O$, or $H^{12}Cr^4O^9$, is deposited when the solution of chromic oxide in excess of alkali is left to itself. It exhibits the same properties as the preceding (Lefort). According to Frémy, these hydrates contain 8 and 9 aq. respectively.

A hydrate containing $Cr^4O^3.7H^2O$, or $H^7Cr^2O^5$, is obtained when a solution of violet chrome-alum is poured into excess of ammonia; the precipitated oxide then turns red and redissolves, and, on heating the ammoniacal solution to a temperature not exceeding 50° C., a greyish-green pulverulent precipitate is formed, having the composition just stated, and dissolving in acids with violet colour. (Lefort.)

d. $Cr^4O^3.9H^2O$, or $H^9Cr^2O^6$.—This hydrate is deposited as a violet powder when the ammoniacal-solution of chrome-alum is left to evaporate in the air or over oil of vitriol. When dry, it forms a greyish-violet, very light powder; when dissolved in acids, it yields red salts. (Lefort.)

According to Frémy, this hydrate is obtained by precipitating a violet chromic salt with ammonia, and drying the precipitate in vacuo. It dissolves in acetic acid, ammonia, and dilute potash-ley. Its properties are liable to considerable alteration from apparently trifling circumstances; thus, by the action of boiling water, or by prolonged contact with cold water, by the action of concentrated saline solutions, by desiccation for several days in the air or in vacuo, and trituration, it is rendered insoluble in liquids in which it was previously soluble. Frémy is of opinion that these alterations result from an allotropic modification of the chromic oxide, and not from loss of water. He applies the term chromic oxide to the oxide which has been rendered insoluble in acetic acid, potash, and ammonia in the manner just mentioned, and metachromic oxide to that oxide which is soluble in these reagents, and is precipitated by ammonia from a violet chromic salt.

A chromic hydrate, much used as a pigment, is the **emerald-green** of Pannetier, $Cr^4O^3.2H^2O = H^4Cr^4O^6$. It is prepared by melting in a crucible a mixture of equivalent quantities of boric anhydride and acid chromate of potassium, whereby chromic borate and borate of potassium are obtained, and treating the fused mass with water, which resolves the chromic borate into boric acid and chromic hydrate. By washing this hydrate and finely triturating it, a brilliant green powder is obtained. (**Guignet**, Rép. Chim. app. 1859, p. 158.)

Arnandon (*ibid.* 201), by acting on acid chromate of potassium with phosphate of ammonium, likewise obtained a very fine green pigment, which appeared to be chiefly a chromic hydrate containing phosphoric acid.

For further details respecting the modifications of chromic hydrate, see Handw. d. Chem. 2^te^ Aufl. ii. [2] 1221.

Chromic Salts.—The salts obtained by dissolving chromic oxide or hydrate in acids, correspond in composition to the oxide itself, containing, that is to say, 3 at. of monatomic acid radicle to 2 at. of chromium, or 3 at. of a diatomic acid radicle to 4 at. chromium, *e.g.* the nitrate $Cr^2(NO^3)^3$, the sulphate $Cr^4(SO^4)^3$. The most definite are the double sulphates, called chrome-alums, consisting of 1 at. chromic sulphate with 1 at. sulphate of an alkali-metal and 12 at. water, corresponding in composition to common alum, and crystallising in the same form, *e.g.* potassio-chromic sulphate,

$$K^2SO^4.Cr^4(SO^4)^3 + 12H^2O, \text{ or } KCr^2(SO^4)^2 + 6H^2O = \left.\begin{matrix}(S^2O^4)^{iv}\\ K(Cr^2)^{'''}\end{matrix}\right\}O^4 + 6H^2O.$$

Chromic salts exhibit two modifications, the **green**, and the **red**, or **violet**, which pass easily one into the other. Thus, a solution of chrome-alum prepared in the cold has a violet colour, which changes to green on heating the solution, but reappears after it has been left to itself for some time. In many chromic salts the nitrate, for example, the change from green to violet takes place very quickly. The green solutions also take a bluish tint when heated with nitric acid. The violet appears to be the normal modification, inasmuch as the others always pass into it after a while; and it is only the violet solutions that yield crystallisable salts, the green solutions, when evaporated, leaving green amorphous masses.

Schrötter (Pogg. Ann. liii. 13) supposes that the change from the violet to the green modification by heat, is the result of a loss of chemically combined water, which is gradually resumed when the green solution is left at rest. **Otto** (Lehrbuch, 3 Aufl. ii. 93) remarks, in opposition to this view, that a red solution of chrome-alum does not turn green when mixed with strong sulphuric acid, provided rise of temperature be prevented.

Löwel (J. pr. Chem. xxxvii. 38) supposes that the different coloured solutions contain different proportions of acid and base, the red solutions containing normal chromic salts, such as $Cr^4(SO^4)^3$, or $Cr^4O^3.3SO^3$, and the green solutions basic salts of the form $Cr^4O^3.2SO^3$. This view receives some support from an observation of **Krüger** (Pogg. Ann. lxi. 218), that when a green solution of chrome-alum, obtained by boiling the salt with a very small quantity of water, is mixed with alcohol, the alcohol takes up a portion of the sulphuric acid, while the separated syrupy liquid contains the salt $K^2O.Cr^4O^3.3SO^3$. This salt, when dissolved in water, does not return to the violet modification unless a quantity of sulphuric acid be added to it sufficient to reproduce the normal salt $K^2O.Cr^4O^3.4SO^3$.

Frémy attributes the change of the violet salts into green by the boiling of their solutions, to a conversion of metachromic oxide into ordinary chromic oxide; this, however, can scarcely be called an explanation.

For the behaviour of chromic salts with reagents see pp. 943, 944.

Chromites.—Chromic oxide unites with protoxides, forming compounds of the form $M^2O.Cr^4O^3$, or MCr^2O^2, which may be called chromites. The best known of these compounds is chrome-iron ore, in which, however, part of the chromium is usually replaced by aluminium and sometimes by iron. Lime, magnesia, and oxide of zinc, when they exist in solution with chromium, are sometimes precipitated by alkalis, when, if the chromium were not present, they would remain dissolved; thus, a solution of chrome-alum mixed with chloride of calcium yields with ammonia a green precipitate, consisting of $2Ca^2O.Cr^4O^3$. On the other hand, bases which would otherwise be precipitated are sometimes retained in solution through the medium of chromic oxide; this is often the case with manganous and ferric oxide. In presence of 80 per cent. ferric oxide, however, chromic oxide is completely precipitated. These circumstances require to be carefully borne in mind in analysis.

Compounds of Chromic Oxide with Ammonia. (**Frémy**, Ann. Ch. Pharm. cx. 226.)—Chromic hydrate is slightly soluble in ammonia, and, under certain circumstances, takes up the elements of ammonia, forming peculiar metallic bases, designated by Frémy as **amido-chromium compounds.**

Chromic hydrate which has been subjected to the action of boiling water does not act upon ammonia; but metachromic hydrate (p. 950), in contact with ammonia, acquires a violet colour, and forms the compound containing $2NH^3.Cr^4O^3$, which gives off the whole of its ammonia when heated.

Ammoniacal salts do not act on metachromic hydrate by themselves; but if ammonia is likewise present, the hydrate dissolves, forming compounds of a beautiful violet colour, which may be obtained in definite form by precipitating with alcohol and rapid drying in vacuo. The compound formed with ammonia and chloride of ammonium dissolves in water with deep violet-red colour. The solution has a scarcely perceptible alkaline reaction, and does not yield any precipitate with nitrate of silver; but if it be heated to the boiling point, ammonia is given off, chromic hydrate separates out, and the remaining liquid then gives a copious precipitate with nitrate of silver. The products of the decomposition are $4NH^4Cl$, $8NH^3$, $3Cr^4O^3$, and H^2O.

If the solution of the amido-chromium compound be left to itself for a while, it decomposes, ammonia being evolved, sal-ammoniac being reproduced, and an insoluble violet body being formed, which separates in round, transparent, iridescent granules. This body likewise contains the elements of chromic oxide and ammonia. It is completely decomposed by boiling water, the products of decomposition being in the ratio of $Cr^4O^3 : 2NH^3 : 12H^2O$. Acids convert it into a basic compound, $Cr^4O^3.8NH^3$, called **roseo-chromammonia**. With sulphuric acid the reaction is:

$$4(Cr^4O^3.2NH^3) + 12H^2SO^4 = \underbrace{(Cr^4O^3.8NH^3).3SO^3}_{\substack{\text{Sulphate of roseo-}\\ \text{chromammonia.}}} + \underbrace{3(Cr^4O^3.3SO^3)}_{\substack{\text{Chromic}\\ \text{sulphate.}}} + 12H^2O.$$

Roseo-chromammonia may likewise be obtained by the action of strong acids in the cold on the soluble amido-chromium compounds precipitated by alcohol from the rose-coloured liquids which are produced by the joint action of ammonia and ammonium-salts on metachromic hydrate. The salts of this base have nearly a wine-red colour; the hydrochlorate crystallises in regular octahedrons, and forms crystallisable double salts with mercuric and platinic chlorides. Pure water decomposes it into two new salts, one crystallising in right rhombic prisms, the other remaining in solution. The bases of these two salts appear to differ from each other, and likewise from that of the hydrochlorate from which they were produced. (Frémy.)

A basic compound containing $Cr^2(CNS)^3.(NH^4)^2O$ is obtained, by adding acid chromate of potassium to fused sulphocyanate of ammonium. (Morland, Chem. Soc. Qu. J. xiii. 252.) (See SULPHOCYANATES.)

BROWN OXIDES OF CHROMIUM. CHROMATES OF CHROMIUM.—These names are applied to certain oxides intermediate between the sesqui- and tri-oxides of chromium. They are obtained by gently heating chromic nitrate; by partial reduction of chromic anhydride with alcohol, sulphurous acid, nitric oxide, or ferrous sulphate; also by boiling a solution of chromate of ammonium; by digesting chromic acid with excess of chromic oxide; by heating chromic anhydride above 250° C.; and by keeping chromic oxide for some time, at 200° C., in contact with the air. A solution of acid chromate of potassium, mixed with ammonia or with alcohol, likewise deposits a brown sediment when exposed to sunlight, but not in the dark.

These brown compounds, when heated, first give off water, if they are hydrated, and at higher temperatures are reduced to chromic oxide; they dissolve in acids, forming brown solutions, from which they are precipitated by ammonia without alteration. They give off chlorine when heated with hydrochloric acid. Alkalis separate chromic acid from them.

The brown oxides, obtained by different processes, exhibit considerable diversity of composition, and it is not exactly known whether they are distinct oxides of chromium or compounds of the sesqui- and tri-oxides. The compound obtained by heating chromic hydrate in contact with the air, which has the composition CrO, or $Cr^4O^3.Cr^2O^3$, is regarded by Krüger as a peroxide of chromium, CrO, because, when heated with sulphuric acid and chloride of sodium, it gives off only chlorine and no chlorochromic anhydride, as all chromates do. A precipitate of the same composition is formed, according to Berzelius, on mixing neutral solutions of chromic chloride and chromate of potassium. The precipitate thrown down by ammonia from a solution of chromic sulphate mixed with acid chromate of potassium, likewise gives off nothing but chlorine when similarly treated; according to Vogel, it is $2CrO.H^2O$. The black substance obtained by heating chromic anhydride to 200° C. is, according to Traube, normal chromate of chromium, $Cr^4O^3.3Cr^2O^3$. It becomes soluble by boiling in water, imparting to the water, first a yellowish, then a deep brown colour.

The precipitate formed on mixing the solutions of chrome-alum and neutral chromate of potassium has, when dried at 100° C., the composition $3Cr^4O^3.2Cr^2O^3.9H^2O$. The oxide obtained by reducing chromic anhydride with alcohol, has, according to Traube, the same composition. It is insoluble in water; dissolves in hydrochloric acid with yellow, in nitric and in hot dilute sulphuric acid with brown colour. The solutions yield with ammonia a precipitate of sesquioxide, while chromic acid remains in solution. Potash quickly resolves it into chromic oxide and chromic acid.

Chromic hydrate digested with excess of chromic acid, yields a dark brown solution, which dries up to a residue soluble in alcohol, and containing, according to Maus, $Cr^4O^3.4Cr^2O^3$, or Cr^4O^5. (Handw. d. Chem. 2^{te} Aufl. ii. [2] 1236.)*

TRIOXIDE OF CHROMIUM. CHROMIC ANHYDRIDE. *Anhydrous Chromic Acid.* Cr^2O^3.—This oxide may be regarded as a constituent of the chromates, the formula of a neutral chromate being $MCrO^2$, or $M^2O.Cr^2O^3$. It is obtained in the free state:

a. By decomposing trifluoride of chromium with a small quantity of water.—The vapour of the trifluoride, evolved by distilling chromate of lead and fluor spar with fuming sulphuric acid, is passed into a large platinum crucible, slightly moistened on the inside and closed with moist paper. The trifluoride is then decomposed by the aqueous vapour, with which the air in the crucible is charged, into hydrofluoric acid and beautiful red needles of chromic anhydride, which fill the crucible.

b. By decomposing a chromate with sulphuric acid.—Chromic acid is easily prepared by pouring 1 vol. of a saturated solution of acid chromate of potassium in a thin stream into 1½ vol. strong sulphuric acid, stirring all the while. As the liquid cools, chromic anhydride crystallises from it in splendid crimson needles often an inch long. The mother-liquor is decanted, and the crystals are drained on a porous tile till they are nearly dry, and then purified by recrystallisation. For many purposes for which chromic acid is used, the presence of a certain quantity of sulphuric acid is not objectionable, so that the purification may be dispensed with.

Bolley (Ann. Ch. Pharm. lvi. 113) prepares chromic anhydride by dissolving a weighed quantity of acid chromate of potassium in a small quantity of boiling water, and adding to the hot solution the exact quantity of sulphuric acid required to form acid sulphate of potassium. The mixture when left to cool, solidifies for the most part into a red granular mass consisting of acid sulphate of potassium with adhering chromic anhydride. The mixture is stirred to cause the granular mass to subside; the solution is decanted; and the residual acid sulphate is washed several times with cold water. There then remains an orange-coloured sulphate of potassium with very little chromic acid, the greater part of that acid being contained in the united solutions. The separation thus effected depends upon the circumstance that acid sulphate of potassium, which dissolves very freely in boiling water (2 pts. of the salt to 1 pt. of water), is but sparingly soluble at ordinary temperatures, and cold water removes sulphuric acid from it with scarcely any potash, leaving neutral sulphate of potassium, while the chromic acid dissolves in the cold water. The solution of chromic acid containing only a small quantity of acid sulphate of potassium is then further concentrated, and the chromic anhydride is precipitated by adding about an equal volume of strong sulphuric acid, which throws it down free from any trace of acid sulphate.

Chromic anhydride may also be prepared by decomposing chromate of lead with strong sulphuric acid, diluting with water after twenty-four hours, to precipitate sulphate of lead, then filtering and evaporating to the crystallising point, or by decomposing chromate of barium with strong nitric acid, filtering the liquid from the resulting nitrate of barium, which is insoluble in the strong acid, and heating the filtrate till the excess of nitric acid is expelled, and crystallising as above.

Pure chromic anhydride forms either a red powder, a red loose woolly mass, or scarlet crystals. It deliquesces in damp air and dissolves in a small quantity of water, forming a dark brown liquid having a sour astringent taste and yellow or brownish yellow on dilution. The solution contains chromic acid, but when evaporated it yields the anhydride: indeed chromic acid is not known in the solid state.

Chromic anhydride melts at 190° C., and begins to decompose at 250°, giving off oxygen and leaving a brown oxide or chromate of chromium, which, when further heated, is reduced to sesquioxide. Chromic anhydride is a powerful oxidising agent, being quickly reduced to sesquioxide of chromium by *sulphydric acid*, *zinc*, *arsenious acid*, *tartaric acid*, *sugar*, *alcohol*, and various other organic bodies, especially when heated. With *sulphydric acid* it forms water and sets sulphur free: $2Cr^2O^3 + 3H^2S = Cr^4O^3 + 3H^2O + S^3$; with *hydrochloric acid* it yields sesquichloride of chromium, water, and free chlorine: $Cr^2O^3 + 6HCl = Cr^2Cl^3 + 3H^2O + Cl^3$. *Sulphurous acid* added to a solution of chromic acid or a chromate throws down a brown chromate of chromium, consisting of $Cr^4O^3.Cr^2O^3$ or CrO. A few drops of *anhydrous alcohol* poured upon chromic anhydride instantly reduce it to sesquioxide, the alcohol sometimes taking fire. A similar reduction attended with incandescence

---

* From recent experiments by Storer and Eliot (Proc. Amer. Acad. v. 192), it appears that there is but one definite oxide of chromium intermediate between Cr^4O^3 and Cr^2O^3, viz. CrO or $Cr^4O^3.Cr^2O^3$. The authors have likewise obtained the analogous compounds $Al^4O^3.Cr^2O^3$, $Fe^4O^3.Cr^2O^3$, $Mn^4O^3.Cr^2O^3$.

takes place when a small quantity of the anhydride is introduced into an atmosphere of alcohol vapour, or of alcohol or ether vapour mixed with sulphide of carbon. Dry *ammonia gas* suddenly directed upon perfectly dry chromic anhydride, renders it incandescent and converts it into chromic oxide, while nitrogen and aqueous vapour are given off. Aqueous chromic acid bleaches vegetable colours.

Chromic acid in the free state is sometimes used practically as an oxidisng agent, but more frequently a mixture of sulphuric acid and chromate of potassium, which yields it.

When crystallised chromic anhydride is added to strong sulphuric acid as long as it dissolves, an ochre-yellow, pasty, very hygroscopic substance is formed, containing. according to Bolley (Ann. Ch. Pharm. lvi. 113), $H^2SO^4.Cr^2O^3$. When exposed to the air, it quickly turns red from separation of chromic anhydride. Schrötter (Pogg. Ann. lix. 616) obtained in like manner a yellow-brown sediment, which he represents approximately by the formula $Cr^4O^3.3SO^3$.

Perchromic Acid. HCr^2O^4 or $H^2O.Cr^4O^7$?—When peroxide of hydrogen dissolved in water is mixed with a solution of chromic acid, the liquid assumes a deep indigo-blue colour, but often loses this colour very rapidly, giving off oxygen at the same time. The same blue colour is produced on adding a mixture of aqueous peroxide of hydrogen and sulphuric or hydrochloric acid to acid chromate of potassium; but in a very short time oxygen is evolved, and chrome-alum is left in solution. For each atom of acid chromate of potassium, $K^2O.2Cr^2O^3$, 4 at. of oxygen are evolved, provided an excess of peroxide of hydrogen be present. We may, therefore, suppose that perchromic acid, HCr^2O^4, is first formed by the union of HO with Cr^2O^3, and afterwards resolved into oxygen and chromic hydrate, $2HCr^2O^4 = H^2O.Cr^4O^3 + O^4$. With ether, perchromic anhydride forms a more stable solution than with water. The ethereal solution, which has a deep blue colour, may be obtained by treating peroxide of barium with hydrochloric or nitric acid, pouring ether on the liquid, gradually adding a solution of acid chromate of potassium, and agitating. Perchromic acid is decomposed by aqueous alkalis, with formation of a chromate and evolution of oxygen; but ammonia and certain organic bases dissolved in ether and added to the ethereal solution of the acid, form stable compounds, from which stronger acids separate the blue acid. The most stable of these compounds is the quinine-salt, which is soluble in alcohol, insoluble in ether, and may be dried without decomposition. (Barreswil, Compt. rend. xvi. 1085.)

The recent investigations of Aschof (*Inaugural-Dissertation über die Uebermangansäure und Ueberchromsäure*, Berlin, 1861) tend strongly to confirm the formula Cr^4O^7 for hypothetical perchromic anhydride. He also finds that when the deep blue ethereal solution of perchromic acid is shaken up with such a quantity of very dilute aqueous potash, that the ethereal layer shall still exhibit a faint blue tint, the aqueous, perfectly neutral liquid below exhibits a peculiar deep bluish-violet tint, which is tolerably stable; but if more potash be added, the colour changes to the light yellow of neutral chromate of potassium, while bubbles of oxygen are given off. Hence it appears that the blue colour belongs to the free acid, the violet to its salts.

According to Storer (J. pr. Chem. lxxxi. 44) the colouring power of perchromic acid is so great, that when a solution of 1 pt. acid chromate of potassium in 30,000 to 40,000 pts. water is shaken up with ether containing peroxide of hydrogen, the ether acquires a perceptible blue tint; he therefore recommends this reaction as a very delicate test for chromic acid. Schönbein (*ibid.* lxxix. 65) applies it as a test for peroxide of hydrogen.

CHROMIUM, OXYCHLORIDES OF. Four of these compounds are known, three of which may be regarded as compounds of sesquioxide and sesquichloride of chromium, and the fourth (the so-called *chlorochromic acid*), as a compound of the trichloride and trioxide. They may also be regarded as derived from the trichloride or sesquichloride by the substitution of oxygen for part of the chlorine.

a. Compounds of Sesquichloride and Sesquioxide of Chromium.—These compounds, of which three have been distinguished, are obtained by evaporating the green solution of the sesquichloride, and heating the residue to different temperatures. By drying at 120° C. a reddish tumefied mass is left, containing $8Cr^2Cl^3.Cr^4O^3 + 24H^2O$, or $Cr^{20}Cl^{24}O^3 + 24H^2O$.

By drying at 150° C., with constant stirring, a greyish red deliquescent powder is obtained, consisting of $4Cr^2Cl^3.Cr^4O^3 + 8H^2O = 3Cr^4Cl^4O + 8H^2O$, or, according to Péligot, $2(CrOCl.HCl) + H^2O$. If this compound be heated to redness, it becomes partially insoluble in water, and the undissolved portion consists of $Cr^2Cl^3.Cr^4O^3$, or Cr^2OCl. It is greyish-red by daylight, green by lamplight, like neutral chromic sulphate. By prolonged ignition in contact with the air, it is completely converted into sesquioxide. (Moberg.)

Péligot (J. pr. Chem. xxxvii. 476) obtained the last mentioned oxychloride by precipitating a green solution of chromic chloride with baryta, evaporating the filtrate to dryness, treating the residue with alcohol, and evaporating in vacuo, as a green deliquescent mass containing $2Cr^2OCl + 3H^2O$. The same oxychloride is obtained by boiling the green solution of the chloride with chromic hydrate, or by prolonged boiling of dilute hydrochloric acid with excess of chromic hydrate.

b. Chlorochromic Anhydride, Chlorochromic Acid. $CrOCl$, or $CrCl^3.Cr^2O^3$.—This compound, discovered by Berzelius, is produced by distilling any anhydrous metallic chloride with an anhydrous chromate and strong sulphuric acid; its formation affords a useful test for the presence of chlorides (p. 903). To prepare it, 10 pts. of decrepitated chloride of sodium are fused with 16·9 pts. of neutral chromate of potassium, and the fused mass, after being broken into lumps, is distilled in a tubulated retort with 30 pts. of strong sulphuric acid, or better with the fuming acid. A brisk action immediately takes place, and the chlorochromic anhydride quickly distils over, without application of heat; it must be collected in a dry receiver kept at a low temperature. The distillate obtained by heating the mixture towards the end of the process, is likely to be contaminated with chromic and sulphuric acids (Wöhler, Pogg. Ann. xxxiii. 343). Another and easy mode of preparation is to distil in a small retort a dry mixture of chromic anhydride and ferric chloride. (Geuther, Ann. Ch. Pharm. cvi. 239.)

Chlorochromic anhydride is a mobile liquid of a splendid blood-red colour by transmitted light, nearly black by reflected light. It has a density of 1·71, and boils at 118° C. When exposed to the air, it diffuses a yellowish-red vapour of specific gravity 5·48. It attacks *mercury* rapidly, detonates with *phosphorus*, sets fire to *sulphur*, *alcohol*, *oil of turpentine*, and other inflammable bodies, and decomposes *sulphydric acid*, with emission of light. In *ammonia gas*, it solidifies with brilliant incandescence, forming a dark brown mass, which remains red-hot for some time. If more ammonia gas be passed over the ignited residue, it changes to a black powder, which, according to Schrötter, is nitride of chromium. When chlorochromic anhydride is distilled with *pentachloride of phosphorus*, chlorine-gas is evolved, and a small quantity of sesquichloride of chromium is formed, but the greater part of the chlorochromic anhydride distils without alteration. It dissolves *iodine* and forms a solid brown mass with *chlorine*. When dropped into *water*, it remains unaltered for a few seconds, but is afterwards decomposed, with violent ebullition, into chromic and hydrochloric acids.

Vapour of chlorochromic anhydride passed through a glass tube heated to low redness is decomposed, with formation of crystalline chromic oxide (p. 948).

The compound described at page 938 as chromochloride of potassium, may be regarded as a compound of chlorochromic anhydride with neutral chromate of potassium, $KCrO^2.CrOCl$.

CHROMIUM, OXYGEN-SALTS OF. See Chromous and Chromic Oxides (pp. 947, 950); also the several Acids.

CHROMIUM, PHOSPHIDE OF. Cr^2P.—Formed when chromic phosphate is strongly ignited with charcoal, or when sesquichloride of chromium is heated in phosphoretted hydrogen gas. The product obtained by the first process is light grey, with faint lustre, and loosely coherent. The phosphide prepared from crystallised chromic chloride forms crystalline scales, like those of the chloride itself; it is black, dissolves but slightly in nitric, nitromuriatic or hydrofluoric acid, oxidises slowly when heated in the air; when it is heated with hydrate of potassium, hydrogen is evolved, and chromate of potassium very slowly formed. (H. Rose, Pogg. Ann. xxxiv. 333.)

CHROMIUM, SULPHIDES OF. The *protosulphide*, Cr^2S, is said to be obtained, mixed with chromic oxide, by heating chromic sulphate in dry oxygen gas (Traube). According to Moberg, protochloride of chromium gives a black precipitate with sulphide of ammonium.

The *sesquisulphide*, Cr^4S^3, is produced by passing vapour of sulphide of carbon over the white-hot sesquioxide; by passing dry sulphydric acid gas over chromic anhydride, oxide, or chloride, heated to bright redness; by heating chromic hydrate with sulphur in vacuo; or by melting chromic oxide with pentasulphide of potassium at a very high temperature. It cannot be obtained by precipitation, the precipitate formed by sulphide of ammonium in solutions of chromic salts, consisting, not of sulphide, but of hydrate.

Sesquisulphide of chromium is dark grey or black, according to the mode of preparation, sometimes shining and crystalline, without metallic appearance, but acquiring an iron-grey metallic lustre by pressure or trituration. When heated in the *air*, it burns to sesquioxide. Heated in *chlorine gas*, it yields chloride of sulphur and sesquichloride of chromium (Berzelius). According to H. Rose, on the other hand, chlorine scarcely acts upon it, even at high temperatures. Heated with *nitre*, it yields sulphate and chromate of potassium. It appears to unite with the acid sulphides, forming sulphur-salts. (Gm. iv. 124.)

A sulphide containing Cr^2S^3 is obtained by heating chromic sulphate in hydrogen gas. Sulphurous anhydride is then evolved and sulphuric acid is formed, together with a blackish-brown, extremely pyrophoric powder, which burns in the air to chromic oxide and sulphurous anhydride. (Kopp, Compt. rend. xix. 1156.)

CHROMOTARTARIC ACID. When tartaric acid in powder is gradually added to a warm aqueous solution of acid chromate of potassium, as long as carbonic acid is evolved, a green solution is formed, which yields by evaporation a vitreous mass, very soluble in water, precipitated by alcohol, and containing, according to Malaguti, $C^4H^4K(Cr^2O)'O^6 + 7aq$. The solution of this salt yields with acetate of lead, a bluish-green precipitate, which, when decomposed by sulphuretted hydrogen, yields tartrate of chromium and hydrogen, or *chromo-tartaric acid*, $C^4H^5(Cr^2O)'O^6$. (Berlin, *Gerhardt's Traité*, ii. 31.)

CHROMULE. Syn. with CHLOROPHYLL.

CHRYIODINE. A product of the decomposition of chrysammic acid by sulphuric acid. (See CHRYSAMMIC ACID.)

CHRYSAMIDE. $C^7H^3(NO^2)^2NO = N.H^2.C^7H(NO^2)^2O$. — A compound formed by boiling chrysammic acid with aqueous ammonia. The acid dissolves; the liquid acquires a deep purple tint, and on cooling deposits chrysamide in needles, which are reddish-brown by transmitted, and metallic green by reflected light. Its solution, treated with dilute acids, does not yield a precipitate of chrysammic acid. With chloride of barium and ammonia, it forms a precipitate of chrysamidate of barium.

According to the formula $C^7H^3(NO^2)^2NO$, which is that proposed by Gerhardt (*Traité*, iv. 253), chrysamide, like amides in general, differs from chrysammate of ammonium, $C^7H(NH^4)(NO^2)O^2$, by 1 at. H^2O. This formula requires 40 per cent. C, 2·4 H, and 20·1 N, whereas the analysis of chrysamide by Schunck and Mulder, gives 37·6 – 38·8 C, 1·85 – 2·35 H, and 18·2 – 19·9 N; but it is probable that the chrysamide analysed was partly converted during the preparation into chrysamidic acid by addition of water, or rather perhaps, that the conversion of the chrysammate of ammonium into chrysamide was not quite complete.

CHRYSAMIDIC ACID. *Ammonio-chrysammic acid.* $C^7H^5N^3O^6 = NH^3.C^7H^2(NO^2)^2O^2$.—This acid, which is isomeric with chrysammate of ammonium, is produced by adding dilute sulphuric or hydrochloric acid to a boiling aqueous solution of chrysamide, and crystallises on cooling in dark-coloured needles, which become olive-green on drying. Its aqueous solution has a deep purple colour, from which it is partly precipitated by acids without change of colour. It gives off ammonia when treated with potash. It is not altered by dilute acids. Strong sulphuric and boiling nitric acid partly convert it into chrysammic acid, with formation of ammoniacal salts.

The chrysamidates, $C^7H^4MN^3O^6$, have the composition of double chrysammates of ammonium and another base, $C^7(NH^4)MN^2O^6$ They resemble the chrysammates in appearance, and in their property of detonating when heated; but are distinguished by giving off ammonia when treated with caustic potash.

Chrysamidate of potassium crystallises in small needles, having a green metallic lustre by reflected light. The *barium-salt* is a red crystalline precipitate.

CHRYSAMMIC ACID. $C^7H^2N^2O^6 = C^7H^2(NO^2)^2O^2$. (Schunck. Ann. Ch. Pharm. xxxix. 1; lxv. 235. — Mulder, *ibid.* lxxiii. 339; lxxii. 285. — Laurent, Compt. chim. 1850, p. 163.—Robiquet, J. Pharm. [3] x. 167, 241). — This acid is produced by the action of nitric acid upon aloes; probably, also by the action of nitric acid on aporetin. (De la Rue and Müller, Chem. Soc. Qu. J. x. 298.)

Preparation from aloes.—1 pt. of aloes is macerated with 8 pts. of nitric acid of specific gravity 1·37; the mass is heated in a large basin till the first violent action has subsided, afterwards in a retort till two-thirds of the nitric acid have been expelled; 3 or 4 pts. more nitric acid and water are added to the residual liquid as long as a precipitate continues to form; and the precipitate, which consists of small shining scales, is washed with cold water till the liquid no longer acquires a yellow, but a faint purple-red colour. The resulting chrysammic acid, still containing aloëtic acid, is triturated with aqueous carbonate of potassium; and the gelatinous mass, which is thereby formed, with evolution of carbonic acid, is washed with cold water till the whole of the carbonate of potassium is removed, then dissolved in boiling water, and the solution filtered; as the liquid cools, the pure potassium-salt separates in golden-yellow laminæ. These crystals are dissolved in boiling water, decomposed by nitric acid, and the chrysammic acid, which separates in the form of a yellow powder, is washed with cold water till the nitric acid is completely removed, and the water is coloured no longer yellow but light purple-red. In treating the chrysammic acid with carbonate of potassium, an excess of the latter must be avoided as far as possible, because it produces a decomposition and reddening of the salt, perhaps from admixture of aloëtic acid.

Chrysammic acid is a yellow powder, often light yellow or greenish yellow, and consisting of small shining scales. It is sparingly soluble in cold, more easily in boiling water. The solution has a deep purple colour, tastes bitter, and reddens litmus. It dissolves easily in alcohol and ether; also in nitric acid and in saline solutions.

The acid detonates violently when subjected to dry distillation, emitting a bright but smoky flame, and diffusing an odour of bitter almonds, together with nitrous vapours. Heated in *chlorine gas*, it gives off hydrochloric acid. Boiled with *caustic potash*, it forms a brown solution from which acids throw down a dark brown precipitate (Schunck's *aloeretic acid;* Mulder's *chrysatic acid*), soluble in pure water, forming soluble salts with the alkalis and earths, insoluble with lead and silver. If the potash is very strong, ammonia is likewise evolved. Chrysammic acid is not attacked by *fuming nitric acid* (Schunck). With strong *sulphuric acid* at the boiling heat, it reacts violently, giving off copious red fumes containing carbonic anhydride, carbonic oxide, sulphurous anhydride, and nitrous anhydride. At the same time a dark violet-coloured substance is deposited (Mulder's *chryiodine*), soluble in potash and reprecipitated by hydrochloric acid, as a gelatinous mass of the same colour. This product appears to be only a mixture, for ammonia separates it into a soluble and an insoluble portion. *Sulphide of potassium* mixed with caustic potash, transforms chrysammic acid into hydrochrysamide: a similar blue substance (Mulder's *chrysindinammonium*) is obtained by decomposing a warm ammoniacal solution of chrysammic acid with sulphuretted hydrogen. *Ammonia* converts chrysammic acid into chrysamide. The acid boiled with water and *stannous chloride*, forms a powder which has a deep violet colour, is nearly insoluble in all solvents ($C^{11}H^{4}N^{2}O^{11}.3SnO^{2}$, according to Mulder), gives off ammonia and assumes a fine blue colour when treated with potash, and is decomposed by nitric acid, yielding aloëtic and chrysammic acids.

The **chrysammates** mostly crystallise in small scales, and exhibit a gold-green metallic lustre on the crystalline faces; those which are amorphous, exhibit the same lustre when rubbed with a hard body. They detonate violently when heated. They are all sparingly soluble, even those of the alkali-metals. In solutions of acetates they dissolve more easily than in water, but less when heated than in the cold.

Chrysammate of Ammonium changes rapidly into chrysamide.

Chrysammate of Barium, $C^7HBaN^2O^6 + 2aq.$, is obtained as a vermilion-coloured precipitate by mixing a solution of the potassium-salt with chloride of barium; also by prolonged boiling of chrysammic acid with chloride of barium. It is quite insoluble in water.

Chrysammate of Cadmium is a dark purple precipitate.

Chrysammate of Calcium is a dark red insoluble powder, exhibiting traces of crystallisation.

Chrysammate of Copper, $C^7HCuN^2O^6 + x\,aq.$, is sparingly soluble in cold, more soluble in boiling water, from which it separates in dark purple needles, exhibiting a golden lustre by reflected light: its solution has a fine purple tint.

Chrysammate of Lead, $C^7HPbN^2O^6$? — Brick-red insoluble powder, obtained by precipitation. According to Schunck, it gives by analysis 34·2 per cent. Pb^2O, the formula requiring 35·78. Mulder found in the precipitate formed with chrysammate of potassium and neutral acetate of lead, 51·6 per cent. Pb^2O, which corresponds to the formula $C^7HPbN^2O^6.PbHO$.

Chrysammate of Magnesium resembles the calcium-salt.

Chrysammate of Potassium, $C^7HKN^2O^6$, crystallises in flat rhomboïdal plates, which exhibit very remarkable relations to polarised light. Light transmitted through one of them, exhibits a reddish-yellow colour and becomes polarised in one plane; but if the crystal be pressed with the blade of a knife on a plate of glass, it spreads on the glass like an amalgam, and a beam of light, transmitted through the thin film thus formed, splits into two rays polarised in planes perpendicular to each other, one having a carmine-red, the other a pale yellow colour. As the thickness of the film increases, the colour of both rays approaches more and more to carmine-red. Still more remarkable phenomena are exhibited by reflected light. An ordinary ray of white light reflected perpendicularly from the face of a crystal or from a film, has the colour of virgin-gold, but as the incidence becomes more oblique, the colour becomes less and less yellow, and at length passes into pale blue. The beam thus reflected is composed of two rays oppositely polarised; the one which is polarised in the plane of reflection remains of a pale blue colour at all angles of incidence; the other, polarised at right angles to the plane of reflection, has a pale-yellow colour at small inclinations, then changes to deep yellow, greenish-yellow, green, bluish-green, blue and violet. (Brewster, *Gerhardt's Traité*, iv. 251.)

Chrysammate of potassium dissolves in 1250 pts. of cold water, easily in boiling water; the solution has a fine red colour.

Chrysammate of Silver. Dark brown precipitate, quite insoluble in boiling water.

Chrysammate of Sodium resembles the potassium-salt in appearance, and possesses the same degree of solubility.

Chrysammate of Zinc crystallises in small dark red needles with gold-green reflection.

CHRYSANILIC ACID. This name was given by Fritzsche to a bluish-red substance obtained by the action of potash upon indigo; according to Gerhardt however (*Traité*, iii. 521), it is nothing but a mixture of isatin, white indigo, and possibly other products. (See INDIGO.)

CHRYSANISIC ACID. $C^7H^5N^3O^7 = C^7H^5(NO^2)^3O$ (Cahours, Ann. Ch. Phys. [3] xxvii. 454).—This acid, which is isomeric with trinitranisol, and may also be regarded as methyl-picric acid, $C^6H^2(CH^3)(NO^2)^3O$, is produced, together with di- and tri-nitranisol, by the action of warm fuming nitric acid on anisic acid (p. 300). When 1 pt. of perfectly dry anisic acid is very gently boiled for half or three-quarters of an hour with 2½ pts. of fuming nitric acid, and the somewhat thick liquid is mixed with 20 times its bulk of water, a yellow oil separates out, which soon coagulates into a solid mass consisting of chrysanisic acid mixed with di- and tri-nitranisol. This mixture, in the form of fine powder, is washed on a filter with ammonia diluted with two or three times its bulk of water, whereby the acid is extracted; the ammoniacal liquid, after being evaporated to one-third, yields on cooling brown needles of the ammonia-salt. These crystals are dissolved in water; the solution mixed with dilute hydrochloric acid; the separated yellow flakes are collected on a filter, repeatedly washed with cold water, dried between bibulous paper, and dissolved in hot alcohol; and the scales which crystallise from the solution on cooling are dried.

Chrysanisic acid forms small golden-yellow rhombic tables, nearly insoluble in cold water, sparingly soluble in hot water, whence it crystallises on cooling. It is but slightly soluble in cold alcohol, but dissolves so abundantly in hot alcohol, that the liquid solidifies on cooling. It dissolves in ether, especially if hot, and crystallises in shining laminæ as the ether evaporates. The acid melts when cautiously heated, and solidifies in the crystalline form on cooling; at a stronger heat, it emits a yellow vapour which condenses in small crystalline scales having a strong lustre.

When boiled with strong nitric acid, it is converted into picric acid. Distilled with aqueous chloride of lime, it yields chloropicrin. By boiling with potash, it is converted into a brown substance.

Chrysanisate of Ammonium.—The solution of the acid in dilute ammonia, evaporated over the water-bath, yields on cooling, small brown needles having a strong lustre. Finer crystals are obtained by spontaneous evaporation of the solution.

Chrysanisate of Potassium, $C^7H^4K(NO^2)^3O$, is obtained by exactly saturating the acid with potash. It is very soluble.

The ammonium-salt produces in solutions of *zinc*-salts, a pale yellow precipitate; with nitrate of *cobalt*, a greenish yellow gelatinous precipitate; with nitrate of *lead*, a copious deposit of chrome-yellow flakes; with *ferric* salts, a pale yellow; with *cupric* salts, a greenish yellow, gelatinous precipitate; and with *mercuric chloride*, yellowish-red flakes, which in dilute solutions appear after a time only.

Chrysanisate of Silver, $C^7H^4Ag(NO^2)^3O$.—The ammonium-salt forms with nitrate of silver, beautiful yellow flakes, which must be washed with water and dried in vacuo.

Chrysanisate of Ethyl, $C^7H^4(C^2H^5)(NO^2)^3O$, is obtained by saturating the alcoholic solution of the acid with dry hydrochloric acid gas, gently boiling for some time, and then adding water. The resulting precipitate is washed, first with ammoniacal, afterwards with pure water, then dissolved in boiling alcohol, and the solution is left to cool. It forms transparent crystalline laminæ of a splendid golden-yellow colour, melting at about 100° C. It is soluble in warm *ether*.

CHRYSANTHEMUM SEGETUM. The ash of this plant has been analysed by Bangert (J. pr. Chem. lxx. 85).—The fresh plant yielded 1·61 per cent., the plant dried at 100° C, 8·52 per cent. ash (63·3 per cent. of which was soluble in water). The ash contained in 100 pts.: 24·86 K^2O, 6·21 Na^2O, 14·08 Ca^2O, 6·96 Mg^2O, trace of manganese, 5·12 SO^3, 12·36 CO^2, 6·16 P^2O^5, 4·68 SiO^2, 16;10 NaCl, with 3·06 sand and charcoal.

CHRYSATRIC ACID. (Mulder, J. pr. Chem. xlviii. 16.) *Aloeretic acid.* (Schunck, Ann. Ch. Pharm. lv. 240.)—An acid produced by heating chrysammic acid with alkalis. Chrysammic acid heated with potash-ley dissolves, forming a brown solution, from which, according to Mulder, acetic acid does not precipitate anything; according to Schunck, however, a brown precipitate is obtained. The solution of the potassium-salt yields with acetate of lead, a brown precipitate containing, according to Tonningen's analysis, 58·71 per cent. Pb^2O, 19·08 C, 0·78 H, and 5·51 N. With chloride of barium, a precipitate is formed, containing 30·80 per cent. Ba^2O, 28·03 C, and 1·82 H. (Schunck). These analyses do not lead to any satisfactory formula.

CHRYSENE, nC^6H^4. (Laurent, Ann. Ch. Phys. [2] lxvi. 136.) — A crystalline hydrocarbon obtained, together with *pyrene*, by the dry distillation of fats, resins, and coal: it may be extracted from coal-tar by redistillation. The products which pass over towards the end of the process, consist of a soft yellow or reddish mass, and a thick oil containing crystalline scales. That which condenses in the neck of the retort is chiefly chrysene, the pyrene passing for the most part into the receiver. By treating the mass in the neck of the retort with ether, the pyrene and certain oily matters are dissolved out, while the chrysene remains in the pulverulent state.

Pure chrysene has a fine yellow colour; it is crystalline, destitute of taste and odour, insoluble in water and alcohol, nearly insoluble in ether: oil of turpentine dissolves it at the boiling heat, and deposits it on cooling in yellow crystalline flakes. It melts at 230° — 235° C., and solidifies on cooling to a deep yellow mass composed of needles. At a higher temperature, it distils with slight alteration.

Nitrochrysene, $nC^6H^3(NO^2)$, produced by the action of strong boiling nitric acid on chrysene, is a red powder, destitute of taste and odour, insoluble in water, nearly insoluble in alcohol and ether. It is dissolved with brown colour by sulphuric acid, partially also by alcoholic potash. When quickly heated in a closed tube, it melts and decomposes with explosion.

CHRYSINDIN. A product of the decomposition of chrysammic acid by ammonia. (Mulder, p. 956.)

CHRYSOBERYL. *Cymophane, Chrysopal.*—An aluminate of glucinum, Al^2GlO^4, or $Gl^2O.Al^4O^6$, generally containing 2 or 3 per cent. of iron. It is usually found in round pieces about the size of a pea, but sometimes in eight-sided prisms with six-sided summits, belonging to the trimetric system. Specific gravity 3·5 — 3·7. Hardness 8·5. Lustre vitreous. Colour various shades of green. Streak uncoloured. Transparent or translucent, sometimes with bluish opalescence internally. Fracture conchoïdal, uneven. It exhibits double refraction, and becomes electric by friction. It is infusible alone before the blowpipe, and very difficult to fuse with borax or phosphorus-salt. With carbonate of sodium, the surface is merely rendered dull. It is not acted upon by acids.

Chrysoberyl is found in Brazil and Ceylon, in rolled pebbles, in the alluvial deposit of rivers; and in granite at Haddaw, Connecticut, Greenfield, near Saratoga, New York, and Orange Summit, Vermont. When transparent and of sufficient size, it is cut into facets and forms a gem.

Crystals of chrysoberyl have been formed artificially by exposing a mixture of alumina and glucina in the proper proportion, together with boracic acid as a flux, to the heat of a pottery furnace for several days, till the boracic acid is completely volatilised (Ebelmen, Ann. Ch. Phys. [3] xxii. 211; xxxiii. 34). [For the crystalline form of the artificial chrysoberyl, see Jahresber. d. Chem. 1851, p. 765.]

A variety of chrysoberyl called *Alexandrite*, from the Ural, exhibits pleochroism, viz. by perfectly white light, an orange-yellow colour in the direction of the longer diagonal of the base, colombo-red along the shorter diagonal, and emerald-green along the principal axis. (Haidinger, Pogg. Ann. lxxvii, 228.)

CHRYSOCOLLA. The Greek name for borax. Applied also to silicate of copper.

CHRYSOHARMINE. Syn. with NITROHARMALINE (*q. v.*)

CHRYSOIDIN. $C^7H^{22}O^4$?—A yellow colouring matter said to exist in very small quantity in asparagus-berries.

CHRYSOLEPIC ACID. Syn. with PICRIC ACID.

CHRYSOLITE. *Peridote, Olivin.* — A silicate of magnesium and iron, $(Mg;Fe)^4SiO^4$, occurring in basalt and lavas, in prismatic crystals of the trimetric system, also massive and compact or granular; colour olive and other shades of green. The term *Chrysolite* includes the transparent crystals of paler colour, while *Olivine* (so-called from the olive-green tint) is applied to imbedded masses or grains of inferior colour and clearness. (See OLIVINE.)

CHRYSOMELANE. Syn. with PLEONAST.

CHRYSOPAL. Syn. with CHRYSOBERYL.

CHRYSOPHANE. See CLINTONITE.

CHRYSOPHANIC ACID. *Chrysophane, Rhubarbaric acid, Rhubarbarin, Rhubarb-yellow, Rhein, Rheic acid, Rheumin, Rhaponticin, Rumicin,* $C^{10}H^8O^3$, or $C^7H^{10}O^2$. The yellow colouring principle of rhubarb and of the wall lichen (*Parmelia parietina*). It was first obtained in an impure state by Herberger, Dulk, and Brandes, afterwards analysed by Rochleder and Heldt (Ann. Ch. Pharm. xlviii. 12), who extracted the pure substance from the *Parmelia;* also by Döpping and Schlossberger (*ibid.* l. 215), by De La Rue and Müller (Chem. Soc. Qu. J. x. 298) and by Thann (Ann. Ch. Pharm. cvii. 324), who obtained it from rhubarb.

Preparation from Parmelia parietina.—The dried lichen is digested in the cold with alcoholic potash or ammonia; the dark red infusion is filtered and mixed with acetic acid; the bulky yellow flocks thereby precipitated are washed with water and redissolved in alcoholic potash, a certain quantity of resin then remaining undissolved; the liquid is again precipitated by hydrochloric acid; and the precipitate, after washing and drying, is redissolved in a small quantity of boiling absolute alcohol. The solution then deposits chrysophanic acid in the crystallised state.

From Rhubarb.—Dulk prepared chrysophanic acid from rhubarb by exhausting the root with alcoholic ammonia, precipitating with subacetate of lead, and decomposing the precipitate, suspended in alcohol, with sulphuretted hydrogen. Schlossberger and Döpping exhaust the pulverised rhubarb with 80 per cent alcohol; evaporate; redissolve in a small quantity of alcohol; add ether to the solution to precipitate certain resinous matters; evaporate the filtered solution to the crystallising point; and purify the chrysophanic acid thus obtained by repeated crystallisation from boiling absolute alcohol.

De la Rue and Müller find that chrysophanic acid may be extracted from rhubarb with much greater facility by means of benzene or the light hydrocarbons obtained from Burmese naphtha, these liquids dissolving it very readily, to the exclusion of the greater part of the other constituents. The crushed root is first macerated in water, which removes about 50 per cent. of soluble matter, then dried and treated with benzene in a Mohr's displacement apparatus; the greater part of the benzene is then distilled off; the residue, which becomes nearly solid on cooling, is pressed between blotting paper to remove the mother-liquor which contains erythroretin and a neutral fat; the crude chrysophanic acid thus obtained is redissolved in hot benzene, which leaves behind a reddish-yellow substance (*emodin*), an additional quantity of which separates as the solution cools; and the chrysophanic acid, which afterwards crystallises out, is further purified by recrystallisation from acetic acid, amylic alcohol, or common alcohol. The residuary rhubarb, thrown away in pharmaceutical laboratories after the preparation of the ordinary alcoholic tincture, may be advantageously used for the preparation of chrysophanic acid by this process, inasmuch as it contains about 2·6 per cent. of that acid, which is but slightly soluble in alcohol, especially in the weak spirit used in the preparation of the tincture. The dark coloured resinous sediment which separates from *Tinctura Rhei* when left to itself, is also rich in chrysophanic acid, and may be subjected to the same treatment.

Thann extracts the root of *Rumex obtusifolius* with ether; distils off the greater part of the liquid; washes the dark yellow-brown mass which separates on cooling with a small quantity of ether; dries it between bibulous paper; boils the residue with 90 per cent. alcohol; dissolves the dirty green granular mass which separates on cooling with alcohol, and precipitates by water, repeating the solution and precipitation several times; purifies the product by treatment with alcoholic ammonia and acetic acid, as in Rochleder and Heldt's process; then crystallises it from alcohol, and lastly from ether by slow evaporation.

Chrysophanic acid crystallises from benzene in six-sided tables (monoclinic), having a pale yellow or orange-yellow colour; from alcohol, amyl-alcohol, or glacial acetic acid, in moss-like aggregates of laminar crystals. It is sparingly soluble in cold water; dissolves in 224 pts. of boiling alcohol of 86 per cent.; in 1125 pts. of the same alcohol at 30° C. It is soluble also in ether and in oil of turpentine, coal-naphtha, benzene, and other hydrocarbons (*vid. sup.*) It melts without decomposition at 162° C. and solidifies in the crystalline form on cooling.

The formula of chrysophanic acid is not quite settled. The analyses by Rochleder and Heldt, and by Schlossberger and Döpping, approach nearly to the formula $C^{10}H^{8}O^{3}$, while those by De la Rue and Müller, and by Thann, agree better with $C^{7}H^{10}O^{2}$.

	Calculation. $C^{10}H^{8}O^{3}$	Rochleder and Heldt.	Schlossberger and Döpping.	De la Rue and Müller.	Thann.	*Calculation.* $C^{17}H^{10}O^{2}$

Chrysophanic acid subjected to dry distillation, partly sublimes, while another portion becomes carbonised. Dilute nitric acid does not appear to act upon it, even at the boiling heat, but the strong acid converts it into a red substance. Strong sulphuric acid dissolves without decomposing it, and water precipitates it from the solution.

The acid dissolves in alkalis with fine deep purple colour: the reaction is very delicate, so that a dilute solution of chrysophanic acid may be used as a test for alkalis. Its solution in potash may be evaporated to dryness without alteration; but at a certain degree of concentration, it deposits blue or violet flocks, which redissolve in water or alcohol, forming red solutions. If the purple solution of the acid in moderately strong potash, together with the flocculent precipitate, be mixed with grape sugar and left to stand in a closed vessel, the alkali being in excess, the colour of the liquid gradually changes to brownish-yellow, and the precipitate disappears: on subsequent exposure to the air, the original colour and the precipitate are reproduced. Hydrate of potassium at its melting point does not act on chrysophanic acid at first; but if the heat be continued or increased, the liquid turns blue and decomposes, emitting an odour like that of octylic alcohol. (De la Rue and Muller.)

With baryta and oxide of lead, chrysophanic acid forms very unstable compounds, which are decomposed even by the carbonic acid in the air. Its alcoholic solution forms with alcoholic subacetate of lead, a reddish-white precipitate, which changes to rose-red by boiling with water; no precipitate with neutral acetate of lead. The ammoniacal solution of chrysophanic acid yields with neutral acetate of lead, a lilac; with alum, a beautiful rose-coloured precipitate. (Thann.)

CHRYSOPRASE. An apple-green or leek-green variety of chalcedony, coloured by nickel.

CHRYSOPRASE EARTH. See PIMELITE.

CHRYSORETIN. A yellow resin obtained from senna-leaves by evaporating the aqueous extract, treating the residue with alcohol, evaporating, dissolving in ether, and again evaporating. It is a mixture of several substances, perhaps containing chrysophanic acid, or a similar acid. (Bley and Diesel, Jahresber. 1848, p. 828.)

CHRYSORHAMNIN. A yellow crystalline substance contained in Persian berries or yellow berries (*graines d'Avignon, Krautz-beeren*), the fruit of *Rhamnus amygdalinus, R. oleoïdes, R. saxatilis, &c.*, especially in the unripe state. According to Kane (Ann. Ch. Phys. [3] viii. 380), it may be extracted from the berries by ether, in which it is easily soluble. It is nearly insoluble in cold water, soluble in alcohol, and contains 58·02 per cent. carbon, and 4·7 hydrogen, whence Kane deduces the formula $C^{23}H^{22}O^{11}$. By boiling with alcohol or water, it is decomposed, yielding another colouring matter, *Xanthorhamnin*, $C^{23}H^{24}O^{11}$, which is soluble in water and alcohol, but insoluble in ether.

Gellatly (Edinb. N. Phil. J. vii. 252), by treating Persian berries with ether, obtained neither chrysorhamnin nor any other characteristic substance; but with alcohol, he obtained a yellow substance crystallising in needles, which appeared to be xanthorhamnin.

According to Bolley (Chem. Soc. Qu. J. xiii. 327), Persian berries yield an abundant extract when treated with *crude ether* (this may perhaps explain the difference between the statements of Kane and Gellatly); and on evaporating the ether, dissolving the residue in alcohol, filtering, and evaporating with addition of water, stellate groups of yellow needles are obtained, which are not altered by repeated solution, boiling, and precipitation. They gave, by analysis of two specimens, 58·87 and 60·239 per cent. carbon, 4·66 and 4·18 hydrogen. The crystals were somewhat soluble in pure ether, sparingly in water, easily in alcohol. The solution gives with neutral acetate of lead, a brick-red precipitate; with nitrate of silver, a blood-red liquid, and afterwards reduced silver. Hence, and from the analysis, Bolley concludes that this substance is quercetin (*q. v.*)

CHRYSOTILE. See SERPENTINE.

CHULARIOSE. Uncrystallisable sugar. (See SUGAR.)

CHUSITE. See OLIVINE.

CHYLE. (Lehmann, *Gmelin's Handbuch*, viii. 216; *Physiological Chemistry*, ii. 281.—Pelouze and Frémy, *Traité*, vi. 162).—Chyle is that portion of the products of digestion which is absorbed by the lacteal vessels terminating in the inner surface of the small intestines, chiefly the jejunum, and thence passing by numerous converging streams into the main trunk of the absorbent system, called the thoracic duct, through which it is gradually poured into the blood of the left subclavian vein, at a short distance before it enters the right side of the heart.

The physical properties of chyle differ according to the nature of the animal to which it belongs, the condition of the animal, whether lately fed or fasting, and the nature of the food which has been taken. Chyle obtained from the thoracic duct during digestion, is an opalescent, milky, yellowish-white or pale red liquid, having a faint, peculiar odour, a somewhat saline and mawkish taste, and very weak alkaline reaction; its specific gravity varies from 1·012 to 1·022. Nine or ten minutes after removal from the vessels, it coagulates; the coagulum, which contracts in from two to four hours, is smaller in bulk compared with the serum than that of blood; it is very soft, easily torn, and sometimes gelatinous. If of a yellow colour, it generally becomes somewhat reddish on exposure to the air, an effect especially observed in the chyle of horses. The serum of chyle, after separation from the coagulum, is never quite clear; it does not usually become turbid when mixed with water; on boiling with water, a milky turbidity appears in the liquid, which, however, generally deposits only a few small clots. Acetic acid often produces a turbidity in the serum, and the filtered liquid when evaporated exhibits on its surface, colourless, transparent films of albuminate of sodium. Ether does not coagulate chyle-serum, but renders it clearer, and between the ether and the serum there is formed a cream-like stratum of a dirty yellowish-white colour.

The chyle of birds, amphibia, and fishes, is nearly transparent and colourless; in horses, it is of a deeper red colour than in any other animals which have been examined with reference to this subject. That of carnivora is comparatively thick and milky; that of herbivora, thinner and more transparent; in cats, it is of a perfectly milky whiteness, whatever may be the nature of their food. During digestion, the chyle is for the most part very turbid; at other times it forms a faintly opalescent fluid, exhibiting a reddish colour only in the thoracic duct.

The morphological elements of the chyle, are: 1. Extremely small granules, consisting of drops of fat enclosed in an albuminous envelope.—2. Granules bound together by a hyaline substance, with or without nuclei, and separate granules with distinct nucleus.—3. The so-called chyle-cells, 0·002 to 0·0055 of a line in diameter, the granules of which mostly become visible on addition of water or acetic acid.—4. The transition forms of the several structures from the more simple to the more complex.—5. A small quantity of coloured blood-cells, especially in the chyle of the thoracic duct.

The *chemical* constituents of chyle are very nearly the same as those of the intercellular fluid of the blood. It is difficult, however, to obtain chyle of constant composition, partly because it varies with the quality and quantity of the food taken, partly because it is always more or less mixed with lymph and blood.

The *fibrin* of chyle is in general less contractile and more gelatinous than that of blood; like the fibrin of many pathological exudations, and that of fish, it sometimes redissolves after coagulation, especially if heated; it is usually destitute of the fibrous structure of blood-fibrin; dissolves very easily in dilute alkalis, carbonic acid, and organic acids; also, after a while, in solution of nitre, and even in sal-ammoniac; from its solution in acetic acid, it is completely precipitated by sal-ammoniac, and from its solution in sal-ammoniac by acetic acid.

The *albumin* of chyle contains a larger amount of alkali than that of blood; it is not rendered turbid, even by very great dilution with water; when boiled, it forms, not coherent flocks, but a milk-white opaque liquid; on evaporation, colourless films form on the surface. The aqueous extract of the chyle-residue has a strong alkaline reaction; on neutralising it with acetic acid, a turbidity is produced, which afterwards redissolves; on subsequently adding ferrocyanide of potassium, a copious precipitate is formed. The original aqueous extract becomes strongly turbid by boiling with sal-ammoniac, also on addition of nitric acid. From chyle-albumin exhausted with water, alcohol, and ether, Lehmann obtained 2·068 per cent. of ash, containing a considerable quantity of alkaline salt which effervesced with acids.

The *fat* of chyle is mostly unsaponified in the smaller lacteals, saponified in the thoracic duct. Chyle does not appear to contain any crystallisable fat.

The existence of *sugar* in chyle is doubtful; that of *bile-constituents*, though probable, has not been demonstrated. *Lactic acid* was found by Lehmann in the chyle of two horses, one of which had been fed two hours before death, with oats, the other with starch.

Chyle is very rich in *alkalis*, combined partly with albumin, partly with lactic and sebacic acids; hence the aqueous solution of the ash has a strong alkaline reaction, and effervesces with acids. *Sulphates of the alkali-metals* are found in the ash, but not in the chyle itself. *Sulphocyanides* are not found. Alkaline phosphates occur in small quantity only, even after the digestion of vegetable food. The *chlorides of sodium* and *potassium* occur in large quantity.

Iron is found in the serum of chyle, but its presence may be due to admixed blood-cells.

During fasting or scanty nutrition, the chyle is poorer in solid constituents, especially fat, and consequently has a turbid but not a milky appearance.

Food rich in fat, whether animal or vegetable, increases the quantity of fat in the chyle.

In the contents of the thoracic duct, two hours after death, of a man killed by drowning, Rees found 98·48 per cent. water, 7·08 albumin, with traces of fibrin, 0·56 aqueous extract, 0·5 alcoholic extract, 0·44 chloride, carbonate, and sulphate of potassium, with traces of phosphate of potassium and oxide of iron, and 0·92 fatty matters.

F. Simon has given the following analyses of the chyle of three horses, the first fed on peas, the other two on oats:

	I.	II.	III.
Water	949·670	928·000	916·000
Fat	1·186	10·010	0·900
Albumin	42·717	46·430	60·530
Fibrin	0·440	0·805	0·900
Hematosin	0·474	trace	5·691
Extractive matter and ptyalin	8·360	5·320	5·265
Chloride and lactate of sodium with traces of calcium-salts	—	7·300	6·700
Sulphate and phosphate of calcium with traces of oxide of iron	—	1·100	0·850
	1002·847	998·965	996·836

The first of these analyses does not, however, admit of direct comparison with the others, as it evidently applies to the organic matter alone.

In the chyle of a cat, Nasse found in 1000 pts.: 905·7 water, and 94·3 solid matter, consisting of 1·3 fibrin, 32·7 fatty matter, 48·9 albumin, globules resembling those of the blood, and extractive matter, 7·1 chloride of sodium, 2·3 other soluble salts, trace of iron, and 2·0 earthy salts.

CHYME. This name, now but little used, was applied to the products of digestion contained in the small intestines, before they have been submitted to the action of the bile and pancreatic juice.

CHYMOSIN. A peculiar nitrogenous matter existing in the gastric juice (*q. v.*); also called *pepsin* or *gasterase.*

CHYTOPHYLLITE. A name applied by Hausmann to certain slags from blast-furnaces, having a broadly laminar structure. They are mainly ferrous silicates, $2Fe^2O.3SiO^2$, the iron being partly replaced by calcium and the silica by alumina. (Jahresber. d. Chem. 1850, pp. 26, 710; 1851, p. 768; 1856, p. 842.)

CHYTOSTILBITE. Radiate blast-furnace slags, having the composition of augite, M^2SiO^3 or $M^2O.SiO^2$, the silica being partly replaced by alumina. (Hausmann, Jahresb. d. Chem. 1856, p. 843.)

CIBOTIUM CUMINGII. An East Indian fern, the hairy stem of which is much used as a means of arresting hæmorrhage. It contains wax, resin, tannic acid, crenic acid, &c. (v. Bemmelen, Viertelj. pr. Pharm. v. 321.)

CICER ARIETINUM. The *Chickpea.*—The hairs of the stem, leaves, and other parts of this plant exude an acid liquid, containing oxalic, acetic, and perhaps malic acid, and, according to Dispan, another acid peculiar to the plant.

CICHORIUM ENDIVIA. See Endive.

CICHORIUM INTYBUS. *Chicory.*—The root of this plant is extensively used for mixing with coffee. The following table exhibits the composition of the organic part of the wild and cultivated varieties, as determined by v. Bibra:

	Cultivated.	Wild.
Fat, insoluble in alcohol	0·07	0·47
Resin	0·84	0·96
Organic acid, precipitable only by subacetate of lead	1·01	1·18
Organic acid, precipitable also by the neutral acetate	2·54	2·51
Sugar	22·08	37·81
Inulin	19·12	10·90
Albumin	0·12	0·15
Tannic acid and volatile oil	trace	trace
Woody fibre	54·21	46·00
	99·99	99·98

The chief difference in the composition of the two varieties appears to be in the relative proportions of inulin and sugar.

Anderson (Highland Agric. Soc. Journ. 1853, p. 61) found in a specimen of chicory cultivated in Yorkshire, 1·6 per cent. nitrogen and 3·6 ash; in another, from the neighbourhood of Glasgow, 1·5 per cent. nitrogen and 6·7 ash.

The leaves contain in 100 pts. 90·9 water and 1·42 ash. (Anderson.)

The composition of the ash of the root and leaves of chicory, as determined by Anderson (*loc. cit.*), and by Graham, Stenhouse, and Campbell (Chem. Soc. Qu. J. ix. 45), is as follows:

Composition of Chicory-Ash *in* 100 pts.

	Root.						Leaves.
	Anderson.		Graham, Stenhouse, and Campbell.				Anderson.

When chicory-root is roasted, several volatile products are given off, and on condensing them, a yellowish liquid is obtained, which has a sharp unpleasant odour, colours the skin permanently dark brown, and contains tannic acid. The aqueous infusion of the roasted chicory contains sugar, a bitter substance, empyreumatic oil, substances which exert a strong reducing action on gold and silver-salts, and organic acids precipitable by lead-salts. It has a disagreeable taste, and, if taken in considerable quantity, produces nausea and sometimes giddiness. (Handw. d. Chem. ii. [2] 24.)

CICUTINE. An alkaloïd but little known, said to exist in the water-hemlock, *Cicuta virosa*. (Polex, Arch. Pharm. xviii. 174. — Wittstein, Buchner's Repert. xviii. 19.)

CIDER. A fermented liquor prepared from apples. Large quantities of it are made in Herefordshire, Devonshire, and the adjoining counties; in the counties of Waterford and Cork in Ireland; in Normandy and Picardy in France; in Belgium; in Germany; and in many parts of the United States.

The apples used in the preparation of cider, ripen at different seasons; in this country, the earliest begin to fall from the trees at the end of September, but the majority do not attain their maturity till about the end of November or the beginning of December.

To make good cider, it is necessary that the apples be quite ripe, to ensure which, it is customary to leave them to ripen for a month or more after gathering; they must not, however, be allowed to get over-ripe, otherwise the quantity of sugar will diminish. The average proportion of sugar in apples at different stages of maturity, has been found to be as follows:

Unripe.	Ripe.	Over-ripe.
4·90	11·00	7·95

To make cider, the apples are thrown into a circular stone trough, usually about 18ft. in diameter, called the *chase*, round which the *runner*, a heavy circular stone, is turned by one or sometimes by two horses; the pulpy fruit or "mist" is then enclosed in coarse hair-cloths, and subjected to pressure by a screw-press, and the brown juice which exudes is poured into casks placed either out of doors, or in sheds where there is a free current of air. Sometimes the dry residue which remains in the bags, is mixed with water, ground again, and the liquor pressed out as before. This latter product makes what is called "water-cider," a thin unpalatable liquor which is given to the labourers early in the year.

About three or four days after the juice has been transferred to the casks, it begins to ferment, the thick heavier parts then subsiding to the bottom, while the lighter become clear bright cider. This is then racked off into another cask, and the sediment is put to strain through linen bags, the liquid which oozes through being restored.

The fermentation is the most delicate part of the process; *slight* fermentation leaves the liquor thick and unpalatable; *rapid* fermentation impairs its strength and durabilty; and *excessive* fermentation makes it sour, harsh, and thin. Other things being equal, that cider will probably prove the best in which the vinous fermentation has proceeded slowly, and has not been allowed to pass into the acetous. If the cider does not clear spontaneously, finings, such as isinglass, eggs, or blood, are added, as in the preparation of beer.

At the beginning of January, the cider is moved into cellars, where, by large growers, it is frequently stored in casks of great capacity, containing 1000, 1500, or even 2000 gallons. In March, the liquor is bunged down; it is then fit for sale, and may be used soon afterwards, though it will greatly improve by keeping. For bottled or effervescing cider, the liquor should be bottled or wired down in the September or October after it is made; some persons prefer an earlier time, the end of April or the beginning of May. A more effervescent liquid is thus obtained, but considerable loss occurs from the bursting of bottles. (*Penny Cyclopædia.*)

The strongest cider contains in 100 volumes, 9·87 volumes of alcohol of 92 per cent.; the weakest, 5·21 volumes. (Brande.)

CIMICIC ACID. $C^{15}H^{28}O^{2} = \left.\begin{matrix} C^{15}H^{27}O \\ H \end{matrix}\right\} O$. (Carius, Ann. Ch. Pharm. cxiv. 147.)—An acid, belonging to the oleic series, contained in the fetid oily liquid ejected by a kind of bug (*Rhaphigaster punctipennis*) when irritated. To prepare it, the insects are treated with strong alcohol, which extracts a brown resinous substance, then macerated with cold ether. The solution thus obtained, yields the acid by evaporation, as a coloured mass; it is purified by converting it into a barium-salt, washing with water and with dilute alcohol, then decomposing the salt with hydrochloric acid, and drying the resulting fat between 40° and 50° C. Two or three hundred of the insects yield about 12 grms. of the fatty acid: the insects freed from fat and dried, weighed 23 grms.

Cimicic acid is a yellow crystalline mass, having a peculiar rancid odour: lighter than water and insoluble therein; very little soluble in alcohol, easily in ether, from which it crystallises by slow evaporation in stellate groups of colourless needles. It melts at 44° C., and, when subjected to dry distillation, yields, besides gases, an oil which solidifies on cooling, and appears to contain some undecomposed acid.

Cimicic acid, treated with *pentachloride of phosphorus*, gives off hydrochloric acid gas, and forms a liquid which, when shaken up with cold water, yields chloride of cimicyl, $C^{15}H^{27}O.Cl$, as a heavy oil, which solidifies at about 44° C., does not crystallise distinctly; dissolves in ether without alteration; is immediately decomposed by alcohol into cimicic ether and hydrochloric acid; and by potash into cimicate and chloride of potassium.

Cimicic acid in alcoholic solution is strongly acid. It dissolves easily, with aid of heat, in aqueous alkalis.

The *cimicates* have the composition $C^{15}H^{27}MO^{2}$. Those of the alkali-metals dissolve in a small quantity of water, but a larger quantity renders the solutions opalescent; they froth with soap-solution, and are precipitated from their aqueous solutions by excess of alkali and by chloride of sodium. The cimicates of the earth-metals and heavy metals are nearly or quite insoluble in water and alcohol; the *lead-salt* only appears to be slightly soluble in ether. The *silver-salt* blackens quickly when exposed to light.

Cimicate of Ethyl, $C^{15}H^{2}(C^{27}H^{5})O^{2}$, obtained by treating chloride of cimicyl with with alcohol and precipitating by water, is a light yellow oil, smelling like the free acid, but stronger: it is lighter than water; does not solidify at 0° C; dissolves readily in alcohol; turns brown when heated.

CIMMOL. Syn. with HYDRIDE OF CINNAMYL (p. 988).

CIMMYL. Löwig's name for the radicle $C^{9}H^{7}$, which he supposes to exist in cinnamic acid.

CIMOLITE or **CIMOLIAN EARTH,** the *cimolia* of Pliny, which was used by the ancients both medicinally and for cleaning cloths, and which has been confounded with fuller's earth and tobacco-pipe clay, is found in the island of Argentiera, the ancient Cimolus, also in Bohemia and in Russia. It is of a light greyish-white colour, acquiring superficially a reddish tint by exposure to the air; massive; of an earthy, uneven, more or less slaty fracture; opaque when shaved with a knife, smooth, and of a greasy lustre; tenacious, so as not without difficulty to be powdered or broken; and adhering pretty firmly to the tongue. Its specific gravity is 2·18—2·30. It is immediately penetrated by water, and splits into thin laminæ of a curved slaty form. Triturated with water, it forms a pappy mass; and 100 grains will give to three ounces of water the appearance and consistence of a thickish cream. If left to dry after being thus ground, it detaches itself in hard bands, somewhat flexible, and still more difficult to pulverise than before.

When it is ground with water, and applied to silk or woollen fabrics greased with oil of almonds, the oil is completely discharged by a slight washing in water, after the stuffs have been hung up a day to dry, without the least injury to the beauty of the colour. It is still used by the natives of Argentiera for the same purposes as of old.

The following are analyses of cimolite: —*a.* From Argentiera, by Klaproth: — *b.* From Alexandrowski in Russia, by Ilimoff: — *c.* A pseudomorph of augite (also called *anauxite*), from the decomposed basalt of Bilin, Bohemia, by Rammelsberg: — *d.* Also called *pelikanite*, from the decomposed granite of Kiew in Russia, by Ouchakoff. (*Rammelsberg's Mineralchemie*, p. 583.)

	SiO^2	Al^4O^3	Fe^4O^3	Ca^2O	Mg^2O	K^1O	P^2O^5	H^2O	
a.	63·00	23·00	1·25	—	—	—	—	12·00	= 99·25
b.	63·52	23·55	—	—	—	—	—	12·00	= 99·07
c.	62·30	24·23	—	0·83	—	—	—	12·34	= 99·70
d.	65·66	22·84	0·44	—	0·56	0·30	0·17	9·31	= 99·28

The first three analyses agree nearly with the formula $2Al^4O^3.9SiO^2 + 6aq.$, which is that of a sesquisilicate, and reducible to $2al^2O.3SiO^2 + 2aq.$ or $al^4SiO^4.SiO^2 + 2aq.$; the fourth contains the same proportions of silica and alumina, but only 4 at. water, $2Al^4O^3.9SiO^2 + 4aq.$

Cimolite appears to be formed from augite containing alumina and magnesia, by the action of infiltrating waters containing carbonic acid, which carry away the magnesia, leaving a hydrous silicate of aluminium; an addition of alnmina may probably take place through the accompanying decomposition of associated felspar. (Dana, ii. 164.)

CINACROL. A product of the action of iodine on wormseed oil (*q. v.*)

CINÆBENE and **CINÆBENE-CAMPHOR.** Constituents of wormseed-oil, according to Hirzel.

CINÆPHANE, CINÆPHENE, CINÆPHONE. Products obtained, according to Hirzel, by the action of iodine on wormseed-oil (*q. v.*)

CINCHONA BARK. *Cortex Chinæ, C. Peruvianus, Quinquina, Cascarilla.*— This name is applied to the bark of the stem and branches of various species of *Cinchona* and other genera of the order *Rubiaceæ*, sub-order *Cinchoneæ*. Those which are obtained from trees of the genus *Cinchona*, are called true cinchona barks; they contain quinine and cinchonine, and have long been known for their antifebrile properties; the barks of the other genera of the sub-order above-mentioned, chiefly *Ladenbergia* and *Exostemma*, are called false cinchona barks; they contain certain proximate principles, likewise found in the true cinchona barks, namely quinic acid, quinovic acid, quinotannic acid, and cinchona-red, but no alkaloïds.

The antifebrile barks were first introduced into Europe from Peru, about the year 1638, by the Countess of Chinchon, wife of the Viceroy of Peru (in whose honour the name *Cinchona* was given to the genus by Linnæus), and a few years later by the Jesuits, and soon acquired great celebrity for the cure of intermittent fevers, being known by the names *Pulvis Comitissæ, Jesuiticus, Cardinalis, Patrum.* The trees which yield them were first recognised and described, about a century later, by the French astronomer La Condamine, in his journey in Peru.

The true cinchonas grow on the wooded slopes of the Cordilleras, from western Venezuela to northern Bolivia, between 10° N. and 19° S. latitude, in a narrow zone extending through a vertical height of about 6400 feet. The barks which are richest in alkaloïds, and are exported (*Cascarillo's fino's*), occur most abundantly from 7° N. to 15° S. latitude, and as they require a cool moist climate, they occupy the region from 11,150 to 6400 feet above the sea-level, whilst those which contain smaller quantities of the alkaloïds, and are therefore not fit for exportation, occupy a warmer and drier zone, between 6400 and 4800 feet in vertical height. With these also are found the *Ladenbergias*, which produce false cinchona barks; they extend also 2000 feet lower through the tropical part of the continent. The *Exostemmas*, which also produce false cinchona barks, inhabit only the hot zone, and are found not only on the continent, but on the islands. Since 1853, the most highly prized cinchonas have been successfully cultivated in Java. The cultivation has also been attempted in Algeria and in India.

The collection of the bark takes place in New Granada at all times of the year; in Peru and Bolivia, only in the dry season. The inner bark of the stems and larger branches, after having been freed from the outer bark, is very carefully dried over a fire for three or four weeks, the weight of the dried products being about one-third of that of the fresh bark. According to Karsten, a tree 60 feet high and 5 feet in diameter, yields about 10 cwt. of dry bark; but such specimens are not often met with. In Ecuador and northern Peru, the bark is taken chiefly from the branches; in southern Peru and Bolivia, from both stems and branches; it is dried in the sun, either in the forest itself, or in drier situations lower down the hill-side. According to Pasteur, the process of drying in the sun is injurious.

The TRUE CINCHONA BARKS known in commerce, are of three kinds, *grey* or *brown*, *yellow*, and *red*. They come to market either in rolled quills, or in flat or hollowed oblong pieces of very various dimensions. They have a more or less splintery-fibrous texture, contain the cinchona alkaloïds, quinine, cinchonine, quinidine, &c., and when coarsely powdered and heated in a test-tube, give off a red tar.

a. Grey Cinchona-barks. *China fusca* s. *grisea*.—These barks are obtained from the branches, and have therefore the form of quills; they are whitish on the outside, with spots of grey, greyish-brown or brown, sometimes black, fine-fissured, of even fracture, splintery only on the inner surface, and contain more cinchonine than quinine. Five species are enumerated, namely, *Huanoco*, *Loxa*, *Pseudoloxa*, *Huamalies*, and *pale Jaen bark*.

b. Yellow or Orange-yellow barks. *Cinchona flava* s. *aurantiaca*.—These barks are obtained from the stems and larger branches, and consist wholly or nearly so of the bass or inner bark; hence they have a fibrous or splintery texture. The alkaloïds contained in them are chiefly quinine and quinidine. The most important species is the Royal, King's or Calisaya bark, of which there are three varieties, viz.—1. Fine Calisaya bark, from *C. Calisaya*, which occurs either in quills or rolls, of 1 to 1½ inches diameter, partly covered with the outer bark, and is then called *Cinchona Calisaya tecta* s. *convoluta;* or in flat plates destitute of outer bark; *C. Calisaya nuda* s. *plana;* this last variety is the richest of all the barks in alkaloïds.—2. *C. Calisaya morada*, from *C. Boliviana;* and 3. *C. Calisaya fibrosa* s. *scrobiculata*. There are four other species of yellow bark, viz. *Cusco bark* (Weddell); *Carthagena* or *Bogota bark*, also called *Cinchona flava fibrosa; Cinchona flava dura;* and *Cinchona Pitaya*.

c. Red Barks. *Cinchona rubra*.—These barks are obtained from the stems and larger branches; they are mostly of brown-red colour, with proportionately thick outer bark, and strong fibrous or splintery bass. They contain more quinine than cinchonine. The species are *Cinchona rubra suberosa*, from *C. succirubra* and *C. rubra dura*.

FALSE CINCHONA BARKS are derived chiefly from trees of the genera *Ladenbergia* and *Exostemma*. They occur in rolls, half rolls, or flat pieces, having a pre-eminently corky texture. They contain no cinchona alkaloïds, and when coarsely pulverised and heated in a test-tube, yield nothing but a dirty yellow or brown tar. The species are: 1. *Cinchona de Para*, obtained from a *Ladenbergia*.—2. *Cinchona nova Granatensis*, from *Ladenbergia oblongifolia* or *magnifolia*. Pelletier and Caventou found in it quinovic acid and an alkaloïd; Winckler found quinovic acid and cinchona-bitter; Hlasiwetz found quinic acid, quinovic acid, quino-tannic acid, and cinchona-red.—3. *Cinchona nova Brasiliensis*, from *Ladenbergia Riedelana*, said to contain quinic and quinovic acids.—4. *Cinchona alba Granatensis*, from *L. macrocarpa*, said to contain alkaloïds, but the statement is doubtful.—5. *Cinchona bicolorata* s. *Atacamez*, s. *Pitoya*, said to contain an alkaloïd pitoyine.—6. *Cinchona Caribæa*, from *Exostemma Caribæum*, contains quinovic acid.—7. *Cinchona Sta. Lucia*, s. *Piton*, s. *Martinicensis*, from *Exostemma floribundum*.

The organic constituents of cinchona barks, are quinine, cinchonine, and two or three isomeric modifications of those bases; aricine; quinic, quinovic and quinotannic acids; cinchona-red; a yellow colouring matter; a green fatty matter; a small quantity of volatile oil, having the odour of the bark; together with starch, gum, and woody fibre.

The ash of cinchona barks consists chiefly of carbonate of lime, and varies in quantity from 0·58 per cent. (in Calisaya bark), to 3·4 (in ash-bark or pale Jaen bark). The acids of the bark are neutralised, partly by the lime, partly by the alkaloïds, and accordingly analysis appears to show that the lime diminishes in proportion as the bark is richer in alkaloïds. Some barks, *e.g.* Calisaya and Huanoco, yield ashes of a green colour, arising from manganate of potassium (Puttfarcken, Pharm. J. Trans. xi. 129). Reichel found in the ash of various cinchona barks, potash, lime, magnesia, silica, and sulphuric acid, with smaller quantities of alumina, iron, manganese, phosphoric acid, and chlorine.

The first chemical examination of cinchona bark appears to have been made in 1785 by Hermbstädt, who obtained from it the calcium-salt of quinic acid, which he designated as *essential salt of quinine*. Schneider in 1807 and Vanquelin in 1808, separated quinic acid from the calcium-salt. Quinotannic acid was discovered by Deyeux in 1793, and obtained in more definite form by Séguin, in 1797. Cinchona-bitter and cinchona-red were obtained from red cinchona bark by Reuss in 1810. At this time, ten years before the discovery of the cinchona alkaloïds, Berzelius made a quantitative examination of a yellowish-brown cinchona bark, and found in it 0·5 per cent. of green soft resin, which quickly hardened, 7·35 quinotannic acid, 6·87 bitter syrupy extract (this contained the alkaloïds), 2·5 quinate of potassium and quinate of calcium, coloured by a small quantity of extractive deposit, 1·25 extractive deposit dissolved out by carbonate of potassium, 2·70 amylaceous gum and 73·75 woody fibre.

Cinchonine appears to have been obtained in an impure state by Gomez of Lisbon in 1811; but its true nature remained unknown till 1820, when Houton-Labillardière first drew attention to the alkaline reaction of the substance obtained by Gomez, and communicated his observations to Pelletier and Caventou, who, in the same year, succeeded in isolating, first **cinchonine**, and afterwards **quinine**, and in proving them to be true vegetable alkaloïds. Several isomeric modifications of these alkaloïds were afterwards discovered and variously named; but according to **Pasteur** (Compt. rend. xxxvi. 26; xxxvii. 110), whose results appear to be the most exact, their number may be reduced to four, namely, **cinchonicine** and **cinchonidine** isomeric with cinchonine; **quinicine** and **quinidine** isomeric with quinine. Cinchonicine and quinicine are produced by the action of heat on cinchonine and quinine respectively; cinchonidine is found in certain cinchona barks, namely, Huamalies, Maracaibo, and Bogota barks, and quinidine is obtained from the mother-liquors of the manufacture of sulphate of quinine.

The three isomeric bases of each group are distinguished by their optical rotatory power. (See the several Alkaloïds.)

Aricine was discovered in 1829 by **Pelletier** and **Corriol** (J. Pharm. xv. 575), in a white cinchona bark, from Arica. Elaborate examinations of various cinchona barks, were published by Reichardt in 1855, and by Reichel in 1856; and lastly, in 1860, De Vry published his researches (*Bonplandia*, viii. 270), on the *Cinchona Calysaya* cultivated in Java.

Cinchona barks are employed medicinally in the form of tinctures and infusions, and were used in this manner, for their febrifuge and tonic properties, long before the discovery of the alkaloïds; but as these qualities are likewise possessed by the pure alkaloïds, and the administration of these alkaloïds is, in many cases, much more convenient than that of the bark in substance, the alkaloïds, especially quinine in the form of sulphate, are prepared from the barks on a very large scale;—the value of a bark to the manufacturer may indeed be said to depend on the quantity of sulphate of quinine that it will yield. It is found, however, that the medicinal properties of the barks are due to the quinic and other acids which they contain, as well as to the alkaloïds, and consequently that the bark in substance cannot in all cases be advantageously replaced by the pure alkaloïd. At one time indeed it was supposed that the medicinal efficacy of the barks depended chiefly on the tannin contained in them. Berzelius wrote in 1831 (*Traité de Chimie*, Paris, v. 587): "There is a law in Sweden in virtue of which, every cinchona bark imported into the country must be tested with infusion of galls, ferric sulphate, solution of gelatin, and tartar emetic; and it is proved, by an experience of sixteen years, that the most efficacious bark is that which gives the strongest precipitate with solution of gelatin and tartar-emetic, in other words, which contains most tannin." The barks which appear to be best adapted for medicinal use are, the flat Calisaya and the Huanoco barks, the former containing the largest proportion of quinine and quinotannic acid, while the latter is richest in cinchonine and quinic acid.

Reactions of Cinchona Barks.—The aqueous infusion of these barks contains the alkaloïds in combination with quinic and the other acids,—and as these salts, and likewise the starch, are more soluble in hot than in cold water, the liquid always becomes turbid on cooling. To extract the whole of the bases, it is necessary to acidulate with hydrochloric or sulphuric acid.

The solution thus obtained may be tested:

1. For **alkaloïds**, which, if present, will give a white precipitate with *tannic acid*, and a yellow crystalline precipitate with *dichloride* of platinum. Another mode of testing for the alkaloïds, is to precipitate the acid solution with carbonate of sodium, and distil the precipitate with excess of caustic alkali, whereby a distillate of chinoline (p. 869) will be obtained.

2. For **Quino-tannic acid.**—White precipitate with *solution of gelatin;* green with *ferric salts;* dirty white with *tartar-emetic.*

3. For **Quinovic acid.**—If this acid is present, *sulphate of copper* first colours the liquid green and then throws down a precipitate, which when collected and washed, has a bitter metallic taste. Winckler proposes to estimate the relative value of cinchona barks by the amount of quinovic acid thus precipitated, inasmuch as the bitterness of a bark depends partly (and in the case of the false barks, exclusively) on the presence of quinovic acid.

4. For **Quinic acid.**—This acid distilled with *sulphuric acid and peroxide of man-*

ganese, yields a distillate of quinone, which is a yellow crystallisable substance, having a pungent odour, and soluble in water. The aqueous solution mixed with ammonia, absorbs oxygen from the air, and assumes, first a brown, then a black colour; a reaction which will indicate the presence of very small quantities of quinic acid. Chlorine-water changes the colour of the aqueous solution of quinone from yellow to bright green. The formation of quinone in this manner is proposed by **Stenhouse** (Mem. Chem. Soc. ii. 226), as a means of distinguishing between true and false cinchona barks, the former alone containing quinic acid. According to other authorities, however (p. 964), this acid is likewise present in some of the false cinchonas.

For the *quantitative estimation* of the alkaloïds, the following methods may be used.

1. One drachm of the finely powdered bark is to be boiled for a few minutes with an ounce of water and half a drachm of strong acetic acid; the liquid filtered off, the residue boiled with a little dilute acetic acid; the liquid again filtered off, and the powder washed; the whole of the liquid evaporated to dryness on a water-bath; and the extract dissolved in a little water and again evaporated, to expel all the free acetic acid. The residue is then to be treated with absolute alcohol and blood-charcoal; the colourless solution filtered off, and the residue exhausted with alcohol. To this solution a few drops of hydrochloric acid are to be added, and next a solution of chloride of platinum as long as it causes turbidity; and the precipitate of chloroplatinate of quinine and cinchonine transferred to a weighed filter, washed with alcohol, dried and weighed. The platinum-salt of quinine contains 44·3 per cent. of that base; the cinchonine-salt 43 per cent. of cinchonine: hence the proportion of the two alkaloïds may be found by the method of indirect analysis (p. 224) (**Duflos**). The alkaloïds might also be precipitated by tannic acid and infusion of gall-nuts.

2. Fifty grains of the pulverised bark is treated with a little diluted hydrochloric acid; the liquid filtered, and the residue washed with a mixture of alcohol and a few drops of the same acid. The dark brown solution is then mixed with a little powder of hydrate of lime, so as nearly to decolorise it, and the precipitate, being thrown on a filter, is washed with alcohol. The liquid contains the organic bases in the free state. It is to be neutralised with hydrochloric acid, diluted with water, and freed from alcohol by evaporation. When it is reduced to two or three drachms measure, the bases are to be thrown down with solution of caustic ammonia; and the precipitate is to be filtered, washed with cold water, dried, and weighed. By digesting it with ether, the quinine is dissolved, and the cinchonine remains behind.

As the alcoholic solution of the bases thrown down by the alkali is often rather strongly coloured, and requires to be decolorised by animal charcoal, alum, protochloride of tin, or hydrate of lead, which occasions loss, Thibouwery extracts the alkaloïds from the precipitate by oil of turpentine, or other non-oxygenated oil, and Rabourdin effects the solution by means of chloroform. The same object is attained, according to Badollier and Scharlan, by subjecting the bark, before treating it with acidulated water, to the action of dilute potash, which removes the tannic acid and the cinchona-red.

3. A quarter of a pound of the coarsely powdered bark is boiled for half an hour with very dilute hydrochloric acid; this operation is repeated on the filtered residue; the final residue is washed with water; the whole of the liquors evaporated to dryness over the water-bath; and the extract redissolved in faintly acidulated water, on the bath. Much of the cinchona-red will remain undissolved. The filtrate is to be concentrated to a small bulk, its bases precipitated by ammonia, and the mixture drained and washed with cold water on a weighed filter. The quinine and cinchonine may then be separated and determined, as above, by means of ether.

4. An ounce of the pulverised bark is digested with five ounces of water containing hydrochloric acid (1½ drachm of acid to a pint of water); the extract is pressed through linen, the operation being repeated three times with each four ounces of the acidulated water; the extracts are then evaporated on the water-bath to six ounces, and the residue washed. From this solution, the alkaloïds are precipitated by soda-ley, till an alkaline reaction is produced; the liquid is then supersaturated with acetic acid; and after the cinchona-red has separated, the nearly limpid liquid is to be filtered. The filtrate is again precipitated with soda-ley; the precipitate left to settle for a day; the clear liquid decanted; the precipitate collected on a small filter, and left to drain well; the still moist filter, with the precipitate, repeatedly shaken up with chloroform; the clear chloroform containing the alkaloïds poured into a tared capsule; the operation repeated three times, with fresh chloroform; and the liquid left to evaporate in the capsule: the net weight gives the total amount of the alkaloïds. The quinine may then be completely dissolved out by ether, the residue in the capsule consisting wholly of cinchonine, which may be weighed. In this manner the relative quantities of the two bases are determined.

A crystalline deposit in the amber-like mass of quinine, indicates the presence of isomeric alkaloïds. To separate cinchonidine (Pasteur's, p. 965), dissolve 1 gramme of the mass in 15 drops of dilute sulphuric acid and 24 drops of water, then add 20 drops of ether and 30 drops of ammonia: the quinine will then dissolve, leaving the cinchonidine, provided the quantity of the latter is not less than 10 per cent. Smaller quantities may be separated by means of ether already saturated with cinchonidine, which will still dissolve quinine. (Zimmer.)

Quinidine may be separated from quinine by the greater solubility of its oxalate in cold water; on treating a solution of quinine with oxalate of ammonium, the quinine is almost wholly precipitated as oxalate, whilst the quinidine-salt remains dissolved.

The following table (p. 968) exhibits the proportions of the alkaloïds contained in different cinchona-barks. The determinations must not however be regarded as very exact, partly because the barks known in commerce by the several names in the table are usually mixtures of different sorts, partly also because different methods of analysis often give different results. According to Wittstock, the precipitation of the bases from the acid extract of the bark by alkalis, is not complete, inasmuch as a somewhat considerable precipitate may afterwards be obtained with tannic acid. Moreover, the precipitates which contain the colouring matter always retain a certain portion of the alkaloïds, and charcoal, if used to decolorise the extract, carries down nearly the whole of the bases; lastly, the separation of quinine from cinchonine by ether is by no means complete.

Reichardt has determined the whole of the constituents of various cinchona-barks. The following is an extract from his table:

Composition of CINCHONA-BARKS.

	Cinchona flava fibrosa.	*Cinchona rubra.*	*Cinchona Huanoco.*	*Cinchona Calisaya plana.*	*Cinchona Calisaya convoluta.*
Quinine	0·705	0·955	0·854	2·701	0·659
Cinchonine	0·245	0·389	2·240	0·264	0·327
Ammonia	0·266	0·100	0·086	0·137	0·123
Quinic acid	6·730	6·019	8·985	6·944	7·245
Quinovic acid	0·196	0·222	1·736	0·684	0·679
Quinotannic acid	0·964	3·179	0·515	3·362	2·162
Cinchona-red	0·933	4·384	—	0·722	0·705
Humic acid	7·729	9·933	27·088	16·355	27·345
Cellulose	59·146	47·777	25·429	45·522	32·653
Total of organic constituents	77·604	74·224	68·514	77·968	72·777
Inorganic constituents	1·634	1·661	2·513	1·224	1·650

In the bark of *Cinchona Calisaya*, cultivated in Java, De Vry found ordinary quinine, crystallisable quinine, quinidine, cinchonine, and quinovic acid. The stem-bark was found to contain 3·90 per cent. of quinine and quinidine; the root-bark 1·136 of the crude alkaloïds; the root-wood 0·06, chiefly cinchonine; the stem-wood 0·08, quinine and cinchonine; the young branches scarcely a trace of alkaloïds; the leaves none. Quinovic acid was found more abundantly in the wood than in the bark; in greatest quantity in the root-wood, and least in the leaves. The bark of *Cinchona lucumæfolia*? yielded only 0·4 per cent. of crude alkaloïds. (Handw. d. Chem. ii. [2] 971.)

CINCHONA-RED. A constituent of cinchona bark, produced from quinotannic acid by atmospheric oxidation. It may be extracted by boiling the bark with water, treating the residue with ammonia, and precipitating the ammoniacal filtrate with hydrochloric acid, washing the resulting precipitate of quinovic acid and cinchona-red, and boiling it with thin milk of lime: quinovate of calcium then dissolves, and cinchona-red remains undissolved in combination with lime. The residue, after being washed with water, is treated with hydrochloric acid; then washed again, dissolved in ammonia, and reprecipitated by hydrochloric acid; dissolved in alcohol, after another thorough washing; and the filtrate evaporated to dryness over the water-bath. (Schwarz, Ann. Ch. Pharm. lxxx. 332.)

Cinchona-red is an amorphous, chocolate-coloured or red-brown, nearly black mass, almost insoluble in water, easily soluble, with red-brown colour, in alcohol, ether, and alkaline lyes, also in strong acetic acid. It is decomposed by heat, giving off copious red fumes, and yielding by dry distillation, an empyreumatic oil, pyrogallic acid, and an impure, volatile, carmine-coloured, aromatic substance, insoluble in water, but soluble in alcohol, ether, and alkaline liquids. (Boissenot, J. Pharm. [3] xxv. 199.)

The formula of cinchona-red is $C^8H^7O^{3·5}$, according to Schwarz; $C^7H^8O^3$ according to Boissenot; it is doubtful whether it has ever been obtained pure. The bark of *Cinchona lancifolia* (Mutis) contains, according to Reichel, from 1 to 2·5 per cent. of it; other cinchona barks are said to contain a larger amount.

Percentage of ALKALOÏDS *in* CINCHONA BARKS.

CINCHONA-TANNIC ACID. Syn. with Quinotannic Acid.

CINCHONETINE. A product of the decomposition of cinchonine by peroxide of lead (p. 974).

CINCHONICINE. $C^{20}H^{24}N^{2}O$. (Pasteur, Compt. rend. xxxvii. 119; Chem. Soc. Qu. J. vi. 273.)—An alkaloïd isomeric with cinchonine, and produced from it under the influence of heat. Any salt of cinchonine may be transformed into the corresponding cinchonicine-salt by heat; but to make the transformation complete and prevent decomposition, the heat must be moderate and the salt must be kept for some time in a resinous state. The change takes place most easily with the sulphate, which, when mixed with a small quantity of water and sulphuric acid, remains melted at a very moderate heat, even after all the water has been expelled, and if kept in this state for three or four hours between 120° and 130° C., is completely converted into sulphate of cinchonicine. Pasteur is of opinion that the resinous state of the fused sulphate is essential to the molecular transformation which takes place. The base may be separated from the sulphate by precipitation with an alkali.

Cinchonicine is nearly insoluble in water, but very soluble in alcohol, whether anhydrous or of ordinary strength. It is very bitter, and is precipitated from its solutions in the form of a liquid resin. It deflects the plane of polarisation to the right. It unites easily with carbonic acid, and separates ammonia from its salts at ordinary temperatures. It possesses febrifuge properties. It is distinguished from cinchonidine by its action on polarised light, and by not being crystallisable; from cinchonine also by the latter property, and by its much greater solubility in alcohol, and greater bitterness.

CINCHONIDINE. $C^{20}H^{24}N^{2}O$, or $C^{19}H^{22}N^{2}O$? (Winckler, Repert. Pharm. [2] xlviii. 384; xlix. 1.—Leers, Ann. Ch. Pharm. lxxii. 147.—Pasteur, Compt. rend. xxxvi. 10; xxxvii. 110; Chem. Soc. Qu. J. vi. 275.—Bussy and Guibourt, J. Pharm. [3] xxii. 401.)—This alkaloïd was discovered by Winckler in a bark resembling the Huamalies cinchona-bark, also in that of Maracaibo. It has likewise been found, accompanied by a small quantity of quinine, in the Bogota cinchona-bark (p. 965). According to Pasteur, it is isomeric with cinchonine, ($C^{20}H^{24}N^{2}O$). The German chemists generally give it the name of *quinidine*.

Preparation.—Cinchonidine is extracted from the barks by the same processes as quinine and cinchonine (pp. 966, 971), and purified by crystallising it several times from alcohol of 90 per cent., till the solution no longer deposits any resinous matter by spontaneous evaporation; then reducing the crystals to fine powder; agitating with ether till the powder no longer exhibits with chlorine-water and ammonia, the peculiar green colouring produced by quinine and quinidine; and finally, recrystallising from alcohol. (See also Zimmer's method of separation, p. 967.)

Properties.—Cinchonidine separates from its alcoholic solution by slow evaporation in anhydrous rhombic prisms, of 94°, hard, with vitreous lustre, and having their faces deeply striated. The same striæ are observed on the faces which replace the obtuse edges of the prism, and the crystals cleave perfectly in the direction of these faces. The prism is modified by two brilliant faces, $\breve{P}\infty$ inclined at an angle of 114° 30′, and resting on the acute edges. The crystals are easily reduced to a perfectly white powder, which becomes electric by friction. They do not taste so bitter as quinine.

Cinchonidine is very sparingly soluble in water, 1 pt. of it dissolving in 2180 pts. of water at 17° C., and in 1858 pts. at 100°. It dissolves in 12 pts. of alcohol of sp. gr. 0·835 at 17°; ether dissolves but little of it, 100 pts. of the solution containing only 0·70 pts. of cinchonidine. (Leers.)

A solution of cinchonidine in absolute alcohol at 13° C., deflects the plane of polarisation of a ray of light strongly to the left; $[\alpha] = -144{\cdot}61°$. (Pasteur.)

According to the analyses of Leers, cinchonidine contains from 76·40 to 76·88 per cent. carbon, 7·70—7·81 hydrogen, and 9·99 nitrogen, whence Leers deduced the formula $C^{19}H^{22}N^{2}O$, requiring 76·60 per cent. C, 7·80 H, and 9·93 N, whereas the formula of cinchonine, $C^{20}H^{24}N^{2}O$, requires 77·9 C, 7·79 H, and 9·09 N. Nevertheless, Pasteur regards cinchonidine as isomeric with cinchonine, inasmuch as it is transformed into cinchonicine by heat, without alteration of weight, in the same manner as cinchonine.

Decompositions.—Cinchonidine melts at 175° C., and solidifies in a crystalline mass on cooling. When strongly heated in contact with the air, it burns with a smoky flame, giving off an odour like that of bitter-almonds or quinine, and leaving a considerable quantity of charcoal. Distilled with hydrate of potassium and a small quantity of water, it yields the same mixture of volatile bases as cinchonine (p. 869). When diffused in fine powder through chlorine-water, it dissolves without perceptible change, even after addition of ammonia.

Commercial cinchonidine is often contaminated with quinidine, the presence of which may be detected either by the green colouring produced by chlorine and ammonia, or by exposing the recently deposited crystals to the air; the crystals of quinidine then effloresce without losing their form, assuming a dull white appearance, while the crystals of cinchonidine retain their transparency.

The *Salts of Cinchonidine* are for the most part more soluble in water than those of quinine; they are very soluble in alcohol, but nearly insoluble in ether. The aqueous solution yields with *alkalis* and their *carbonates*, white pulverulent precipitates, which become crystalline when left at rest; and are insoluble in excess of the reagent. With *phosphate of sodium*, *mercuric chloride*, and *nitrate of silver*, they produce white precipitates; light yellow with *chloride of gold*, orange-yellow with *dichloride of platinum*, and brown with *chloride of palladium*. With *sulphocyanate of ammonium* they yield a white, and with *tannin*, a dirty yellow precipitate.

Hydrochlorates of Cinchonidine.—The neutral salt, $C^{20}H^{24}N^2O.HCl$ (at 100° C.), forms large rhomboïdal prisms, having a vitreous lustre, soluble in 27 pts. of water at 17° C., very soluble in alcohol, nearly insoluble in ether.

	Analysis (mean).	*Calculation.*	
	Leers.	Leers.	Gerhardt.
	At 100° C.	$C^{19}H^{22}N^2O.HCl.aq.$	$C^{20}H^{24}N^2O.HCl.$
Carbon . . .	64·34	64·19	69·67
Hydrogen . .	7·17	7·13	6·97
Chlorine . .	10·05	10·54	10·31

The *acid salt*, $C^{20}H^{24}N^2O.HCl + aq.$, forms large crystals, very soluble in water and in alcohol; after drying over oil of vitriol, they give off 5·8 per cent. water; the calculated quantity for 1 at. is 5·1, according to Leers' formula; 4·5 according to that proposed by Gerhardt.

	Analysis (mean).	*Calculation.*	
	Leers.	Leers.	Gerhardt.
	At 100° C.	$C^{19}H^{22}N^2O.2HCl.$	$C^{20}H^{24}N^2O.HCl.$
Carbon . . .	58·30	57·93	63·32
Hydrogen . .	7·12	6·97	6·33
Chlorine . .	18·98	18·99	18·73

Chloromercurate of Cinchonidine, $C^{20}H^{24}N^2O.2(HCl.HgCl)$? crystallises in shining nacreous scales, sparingly soluble in cold water. Analysis gave 34·77 per cent. C, 4·01 H, 31·9 Hg, and 22·46 Cl, agreeing nearly with $C^{19}H^{22}N^2O.2(HCl.HgCl)$, which requires 34·52 C, 3·83 H, 31·97 Hg, and 22·63 Cl. The formula $C^{20}H^{24}N^2O.2(HCl.HgCl)$ would require 35·8 C, 3·51 H, 29·8 Hg, and 21·18 Cl.

The *chloroplatinate*, $C^{20}H^{24}N^2O.HCl.PtCl^2$? is an orange-coloured precipitate, containing at 110° C. from 27·05 to 27·17 per cent platinum, whence Leers deduces the formula $C^{19}H^{22}N^2O.HCl.PtCl^2 + 2aq.$, requiring 27·04 per cent. Pt, whereas Gerhardt proposes $C^{20}H^{24}N^2O.HCl.PtCl^2$, which requires 27·36 per cent. It is not probable that the salt should retain 2 at. of water at 110° C.

Chlorate of Cinchonidine, obtained by decomposing the neutral sulphate with chlorate of potassium, crystallises from alcohol in long silky prisms, grouped in tufts. It melts at a gentle heat, and decomposes with loud explosion at a higher temperature.

Hydrofluate of Cinchonidine forms silky needles, very soluble in water.

Hyposulphite of Cinchonidine, obtained by precipitating the neutral sulphate with hyposulphite of sodium, crystallises on cooling, in long asbestos-like needles, sparingly soluble in water, easily in alcohol.

Nitrate of Cinchonidine is obtained in mammellated crusts, having the appearance of enamel, and very soluble in water.

Sulphates of Cinchonidine.—The *neutral salt*, $2C^{20}H^{24}N^2O.H^2SO^4$ (at 100° C.), crystallises in long silky needles grouped in stars, neutral to test-paper. One pt. of the salt dissolves in 130 pts. water at 17° C., and in 16 pts. at 100°; it is very soluble in alcohol, nearly insoluble in ether (Leers); it dissolves at mean temperatures in 30—32 pts. absolute alcohol, and in 7 pts. alcohol of 90 per cent. (Bussy and Guibourt.)

Analysis (mean).	*Calculation.*	
Leers.	Leers.	Gerhardt.

64·75	65·25	67·20
7·05	6·95	6·72
12·01	12·08	11·20

The *acid sulphate* is obtained by evaporation in vacuo, as a crystalline mass composed of shining asbestos-like needles.

Sulphate of Iodocinchonidine.—Cinchonidine forms with iodine and sulphuric acid, a crystalline salt, which acts upon light in the same manner as the corresponding salts of quinine and cinchonine, also two other salts, one yellow and the other olive-green, which do not exhibit these peculiar optical properties. (W. B. Herapath, Chem. Soc. Qu. J. xi. 130.)

Acetate of Cinchonidine crystallises in long silky needles, which are very sparingly soluble in cold water, and give off part of their acid on drying. The *butyrate* and *valerate* form mammellated crusts, having the odour of the respective acids.

The *citrate* forms small needles, having but little lustre. The *hippurate* crystallises in silky needles, having the aspect of fern-leaves, very soluble in water and alcohol. The *oxalate* separates on cooling in long silky needles, from a mixture of the hot alcoholic solutions of oxalic acid and cinchonidine. The mother-liquor deposits by spontaneous evaporation, dull white, mammellated crusts. The *quinate* crystallises in small needles, very soluble in water and in alcohol. The *neutral tartrate* forms beautiful needles, having a vitreous lustre. The *acid tartrate* forms small nacreous needles, very sparingly soluble in water.

Methyl-cinchonidine, $C^{19}H^{21}(CH^3)N^2O$, or $C^{20}H^{23}(CH^3)N^2O$? (Stahlschmidt, Ann. Ch. Pharm. xc. 218.) The *hydriodate* of this base is obtained by the action of iodide of methyl on cinchonidine. It crystallises in colourless shining needles, containing:

	By Analysis.	*By Calculation.*

Oxide of silver converts it into a basic compound resembling methyl-cinchonine.

CINCHONINE. $C^{20}H^{24}N^2O$, or $C^{40}H^{24}N^2O^2$. (Fourcroy, Ann. Chim. viii. 113; ix. 7.—Vauquelin, *ibid.* lix. 30, 148.—Gomez, Edinb. Med. and Surg. Journal, 1811, Oct. p. 420.—Pfaff, Schw. J. x. 365.—Pelletier and Caventou, Ann. Ch. Phys. xv. 291, 337.—Pelletier and Dumas, *ibid.* xxiv. 169.—Liebig, Ann. Ch. Pharm. xxvi. 49.—Regnault, Ann. Ch. Phys. lxviii. 113.—Gerhardt, Rev. scient. x. 886; *Traité*, iv. 105.—Laurent, Ann. Ch. Phys. [3] xix. 363.—Strecker, Compt. rend. xxxix. 58.)

This alkaloïd exists, together with quinine, in most of the true cinchona-barks, most abundantly in *Cinchona Huanoco*, *C. Huamalies*, *C. rubiginosa*, and *C. flava fibrosa*. (See table, p. 968.)

Preparation.—All methods of extracting the alkaloïds from cinchona-barks consist in treating the bark with a dilute acid, and precipitating the alkaloïds from the acid extract, with lime or carbonate of sodium. The general mode of proceeding is as follows:

The bark, reduced to powder, is boiled for an hour or less with 8 or 10 times its weight of water, acidulated with 10 per cent. of strong sulphuric acid, or better, with 25 per cent. of hydrochloric acid; the decoction is strained through a cloth; and the residue is boiled a second and sometimes a third time, with more and more dilute acid till the marc is completely exhausted. The extracts, after cooling, are mixed with a slight excess of milk of lime, added by small portions, to precipitate the alkaloïds together with the colouring matter. The precipitate is left to drain, and submitted to a gradually increasing pressure, the liquids which run off from the cloths and from the press being collected in a single vessel; they yield after a while a fresh deposit. The pressed cake is now dried, and macerated with alcohol in a closed vessel heated over a water-bath. The strength of the alcohol used depends upon the quality of the bark under treatment. For Calisaya bark, which is very rich in quinine, alcohol of 75 to 80 per cent. is sufficiently strong; but barks which contain a smaller proportion of quinine, require alcohol of 85 to 90 per cent., because cinchonine is much less soluble in weak alcohol than quinine.

If the bark is rich in cinchonine, and the quantity of alcohol used is not too large, the cinchonine is deposited in the crystalline state as the alcoholic extracts cool, and an additional quantity may be obtained by decanting the supernatant liquid, and distilling off half or two-thirds of the alcohol. The quinine remains in the mother-liquor and may be separated in the form of sulphate. (See Quinine.)

If on the other hand the bark contains more quinine than cinchonine, it is best to treat the alcoholic extract with dilute sulphuric acid, and remove the alcohol by distillation. The greater part of the sulphate of quinine then separates in a crystalline mass, the rest, together with the sulphate of cinchonine, remaining in the mother-liquor. By precipitating the two alkaloïds with carbonate of sodium, redissolving in sulphuric acid, and recrystallising, a further separation may be effected; or they may be precipitated by a caustic alkali, and separated by ether, which dissolves the quinine much more readily than the cinchonine (p. 966).

Carbonate of sodium is a better precipitant for the alkaloïds than lime, because they are soluble to a slight extent in lime-water and chloride of calcium.

Oil of turpentine, fixed oils, and chloroform may be used instead of alcohol for dissolving the alkaloïds from the crude precipitate thrown down by lime or soda; and these solvents have the advantage of not taking up so much of the colouring matter as alcohol does (p. 966); but they are better adapted for the preparation of quinine than of cinchonine, which is but sparingly soluble in either of them. (See QUININE.)

Properties.—Cinchonine deposited by slow evaporation of its alcoholic solution, forms colourless, shining, quadrilateral prisms or needles, which are anhydrous. It has a peculiar bitter taste, which however is slow in developing itself, on account of the sparing solubility of the substance. It is insoluble in cold water, and requires for solution 2500 parts of boiling water. In alcohol it is much less soluble than quinine, the solubility increasing however with the strength of the alcohol and the temperature. According to Duflos, strong alcohol dissolves 3 per cent of its weight of cinchonine. It is insoluble in ether, slightly soluble in chloroform, volatile oils and fixed oils.

The solutions of cinchonine have an alkaline reaction, and deflect the plane of polarisation of a luminous ray strongly to the right. An alcoholic solution acidulated with sulphuric acid gives $[\alpha] = + 190 \cdot 40°$; acids produce a temporary decrease of the rotatory power. Cinchonine possesses febrifuge properties, but in a much lower degree than quinine.

The following are the mean results of the analyses of cinchonine by various chemists.

	Calculation.		Liebig.	Regnault.	Gerhardt.	Hlasiwetz.	Laurent.
C^{20} . .	240	77·93	76·36	76·78	77·63	77·97	77·29

O . .	16	5·19	7·40	6·08	—	—	—
$C^{20}H^{24}N^2O$	308	100·00	100·00	100·00			

Laurent assigned to cinchonine the formula $C^{19}H^{22}N^2O$. According to Schützenberger (Jahresber. d. Chem. 1858, p. 372), the name cinchonine is applied to bases of different constitution; one sample which he analysed yielded numbers agreeing with the formula $C^{19}H^{22}N^2O^2$.

Cinchonine melts at 165° C. forming a colourless liquid, which becomes crystalline on cooling; at a higher temperature, it partly sublimes, exhaling an aromatic odour. According to Hlasiwetz, cinchonine may be sublimed in hydrogen or ammonia gas in the form of shining prisms more than an inch long. Heated with *sulphuric acid and peroxide of lead*, it yields a red substance, cinchonetine, which has not been examined (Marchand, J. Chim. méd. x. 362). Other oxidising agents, *e. g.* nitric acid, permanganate of potassium, and a mixture of sulphuric acid and peroxide of manganese, do not exert much action upon it; neither is it decomposed in a definite manner by emulsin (Hlasiwetz). With *nitrous acid*, it forms a base containing 1 at. oxygen more than cinchonine, and isomeric with quinine, but approaching more nearly to cinchonine in its properties (Schützenberger, Jahresber. f. Chem. 1858, p. 371). It dissolves in *fuming sulphuric acid*, yielding sulpho-cinchonic acid, which forms a soluble barium-salt, $C^{20}H^{22}BaN^2O.SO^4$ (Schützenberger.) With *chlorine* and *bromine*, it forms several substitution-bases, as well as a resinous substance. With *chlorine* and *ammonia*, it does not exhibit the green colouring which is characteristic of quinine. With *iodine* and *iodated potassic iodide* it behaves like quinine. Distilled with *hydrate of potassium*, it yields chinoline, together with several other volatile bases (p. 869).

Beta-cinchonine.—Schwabe (J. Pharm. [3] xxxviii. 389), has obtained from commercial quinoïdine (a product of the alteration by heat of quinine, cinchonine, &c. found in the mother-liquors of the preparation of sulphate of quinine), an alkaloïd isomeric with cinchonine, but differing from it in many properties. This β-cinchonine is contained in the portion of quinoïdine which is sparingly soluble in alcohol; and the sulphate is obtained therefrom by dissolving the substance in dilute acid, precipitating with ammonia, treating the washed precipitate with cold alcohol of specific gravity 0·845, again dissolving it in dilute sulphuric acid, and crystallising. The base separated from the sulphate crystallises from boiling alcohol by spontaneous evaporation in rhombic combinations, $\infty P . \infty \breve{P} \infty . oP$ ($\infty P : \infty P = 119°$). The crystallised as well as the precipitated base is anhydrous, and melts at 150° C. β-cinchonine is more soluble in water, alcohol, ether, and chloroform than ordinary α-cinchonine. The following table gives the quantities of these several solvents required to dissolve 1 pt. of α and β cinchonine, as determined by Schwabe.

	α-Cinchonine.	*β-Cinchonine.*
Water, cold	insoluble	insoluble
Water, hot	2500	scarcely soluble
Alcohol, cold	—	173
Alcohol, hot	30	43
Ether	insoluble	378
Chloroform	40	268

The alcoholic solution of β-cinchonine is dextro-rotatory.

β-cinchonine is precipitated white from the solutions of its salts by caustic or carbonated alkalis, the precipitate being somewhat soluble in excess of the reagent, and disappearing when shaken up with ether. A solution of the base containing tartaric acid is not precipitated by acid carbonate of sodium. A neutral solution of the sulphate mixed with chlorine-water and then carefully with ammonia, exhibits a yellow colour. With ferrocyanide of potassium and chlorine, a red colouring is produced, turning green on addition of ammonia. Quinine-solutions thus treated, exhibit a dark red colour; ordinary cinchonine and quinidine, wine-yellow.

Salts of Cinchonine.—Cinchonine dissolves readily in acids. The salts are bitter and are very much like the corresponding salts of quinine, but for the most part more soluble in water and in alcohol. Ordinary cinchonine forms both acid and neutral salts; β-cinchonine apparently only neutral salts.

ACETATE OF CINCHONINE.—A solution of cinchonine in acetic acid always exhibits an acid reaction, however great may be the excess of cinchonine contained in it; but if concentrated by heat, it deposits on cooling, small sparingly soluble crystals, which exhibit no acid reaction after washing. If the liquid be slowly evaporated to dryness, a gummy mass is obtained, which is decomposed by water into an acid salt which dissolves and a neutral salt which remains at the bottom. (Pelletier and Caventou.)

Acetate of β-Cinchonine forms right-angled four-sided prisms, like those of the sulphate and hydrochlorate. (Schwabe.)

ARSENATE of CINCHONINE.—Very soluble; difficult to crystallise.

CARBONATE OF CINCHONINE.—Cinchonine dissolves in aqueous carbonic acid more easily than in pure water; but the solution does not yield a crystallised carbonate.

CHLORATE of CINCHONINE, $C^{20}H^{24}N^2O.HClO^4$.—White bulky crystalline tufts; melts at a gentle heat, and decomposes with explosion at a higher temperature. (Serullas.)

CHROMATE OF CINCHONINE.—Obtained as a yellow amorphous precipitate, adhering to the glass, but becoming crystalline after a while when a solution of sulphate of cinchonine is mixed with acid chromate of potassium. It is decomposed by water and alcohol. (Elderhorst.)

CYANURATE OF CINCHONINE.—A solution of cinchonine in a boiling saturated solution of cyanuric acid deposits rhomboïdal prisms, sparingly soluble in water, insoluble in alcohol and ether. The salt gives off 17·79 per cent. water at 100° C; and decomposes at 200°, exhaling an odour of bitter almonds. (Elderhorst.)

FERRICYANATE OF CINCHONINE, $C^{20}H^{24}N^2O.3HCy.Fe^2Cy^3 + 2aq$.—Orange-yellow precipitate, obtained by mixing the aqueous solutions of hydrochlorate of cinchonine and ferricyanide of potassium. After drying in the air, it undergoes no alteration at 100° C. (Dollfus, Ann. Ch. Pharm. lxv. 224.)

FERROCYANATE OF CINCHONINE, $C^{20}H^{24}N^2O.4HCy.2FeCy + 2aq$.—Lemon-yellow precipitate produced on mixing the alcoholic solutions of cinchonine and ferrocyanic acid. It is very sparingly soluble in alchol, and when heated, either alone, or with water, is decomposed, yielding hydrocyanic acid and a blue residue (Dollfus). *Ferrocyanate of β-cinchonine* is sparingly soluble and crystallisable. (Schwabe.)

FORMATE OF CINCHONINE.—Very soluble; crystallises from a syrupy solution in silky needles.

GALLOTANNATE OF CINCHONINE.—Yellowish-white powder, very little soluble in cold, more soluble in boiling water, whence it separates in transparent grains on cooling.

HIPPURATE OF CINCHONINE.—Uncrystallisable.

HYDROCHLORATE OF CINCHONINE.—The *neutral salt,* $C^{20}H^{24}N^2O.HCl$, obtained by exactly saturating cinchonine with weak hydrochloric acid; crystallises in transparent shining rhomboïdal prisms; melts at 100° C.; dissolves easily in water and in alcohol, but is insoluble in ether. The aqueous solution possesses dextro-rotatory power; $[\alpha] = +139{\cdot}50^\circ$ (Bouchardat). When subjected to electrolysis, it yields chlorocinchonine, together with chlorine, oxygen, and hydrogen. (Babo.)

Hydrochlorate of β-cinchonine, $C^{20}H^{24}N^2O.HCl + 2aq.$, crystallises apparently in rhombic combinations, $\infty P . \infty \breve{P} \infty . oP$, in which $\infty P : \infty P = 126\frac{1}{2}^\circ$. It dissolves in 22 pts. of cold, 3·2 pts. of hot water; in 1 pt. of cold, ½ pt. of boiling alcohol, and in 550 pts. of ether.

Acid hydrochlorate of cinchonine, $C^{20}H^{24}N^2O.2HCl$, is produced by exposing cinchonine to hydrochloric acid gas, and is obtained crystallised by pouring a slight excess of the acid on cinchonine, and dissolving the product in a mixture of water and alcohol. The solution left to evaporate very slowly in an unclosed bottle, deposits very well-defined rhombic tabular crystals, having the acute angles truncated, $\infty \breve{P} : \infty P = 101^\circ$; $\breve{P} \infty : oP = 137$ to 138°. It is very soluble in water, rather less in alcohol; reddens litmus. The solution is dextro-rotatory.

Chlorine passed into a solution of this salt, forms a deposit of acid hydrochlorate of dichlorocinchonine.

Chloromercurate, $C^{20}H^{24}N^2O.2(HCl.HgCl)$.—On mixing a solution of cinchonine in strong alcohol containing hydrochloric acid with a solution of mercuric chloride also in strong alcohol, the mixture solidifies after a while to a mass of small needles, nearly insoluble in cold water, ordinary alcohol, and ether, moderately soluble in boiling water, and in warm alcohol, easily soluble in strong hydrochloric acid. The salt may be dried at 100° C. without alteration.

Chloroplatinate, $C^{20}H^{24}N^2O.2(HCl.PtCl^2)$.—Light yellow precipitate, obtained by adding dichloride of platinum to a solution of acid hydrochlorate of cinchonine. With an alcoholic solution of cinchonine containing hydrochloric acid, the precipitate is crystalline and nearly white, and dissolves after prolonged boiling with water, the solution as it boils, depositing, first a whitish pulverulent precipitate, afterwards beautiful crystals of a deep orange colour. The salt contains, according to Hlasiwetz, 33·1 per cent. C, 3·6 H, and 27·36 Pt, the formula requiring 33·0 C, 3·3 H, and 27·36 Pt.

Chloroplatinate of β-cinchonine, $C^{20}H^{24}N^2O.HCl.PtCl^2$, crystallises on mixing the alcoholic solutions of its component salts, in rhombic combinations, $\infty P . \infty \breve{P} \infty . oP$, in which $\infty P : \infty P = 119$ (approximately). (Schwabe.)

HYDROCYANATE OF β-CINCHONINE, obtained by precipitation with cyanide of potassium, is amorphous, anhydrous, insoluble in water and alcohol. (Schwabe.)

HYDROFLUATE OF CINCHONINE, $C^{20}H^{24}N^2O.2HF$.—A solution of recently precipitated cinchonine in dilute hydrofluoric acid, deposits colourless prisms when concentrated. The salt crystallises easily from dilute alcohol in rhomboïdal prisms terminated by octahedral faces. After drying at mean temperature, it gives off 2·8 per cent. water at 160° C.; at a high temperature, it acquires a fine purple tint, yields a red sublimate, gives off hydrofluoric acid, and becomes carbonised.

HYDRIODATE OF CINCHONINE, $C^{20}H^{24}N^2O.HI + aq.$ (Regnault.)—Much less soluble than the hydrochlorate. Crystallises easily in nacreous needles. Its solution is precipitated by mercuric chloride and cyanide. *Hydriodate of β-cinchonine* is easily soluble in water and in alcohol. (Schwabe.)

HYPOSULPHATE OF CINCHONINE.—Crystallisable; resembles the quinine-salt (*q.v.*)

HYPOSULPHITE of CINCHONINE.—Obtained by precipitation in small needles; very sparingly soluble in cold water. (Winckler.)

IODATE OF CINCHONINE, $C^{20}H^{24}N^2O.HIO^3$ (at 105° C.).—Long silky fibres, very soluble in water and alcohol. Explodes with violence at 120° C.

NITRATE OF CINCHONINE, $C^{20}H^{24}N^2O.HNO^3 + aq.$ (Regnault.)—Obtained by dissolving cinchonine in dilute nitric acid. If the solution is rather concentrated, part of the nitrate separates in oily globules, which, if covered with water, are converted in a few days into a group of oblique rectangular prisms, very soluble in water. The solution is dextro-rotatory, $[\alpha] = +172·48°$ (Bouchardat). When decomposed by the electro-current (from six Bunsen's cells), it gives off oxygen at the positive pole, mixed after a while with carbonic acid and oxides of nitrogen, and at the negative pole, a mixture of hydrogen and nitrogen containing a little ammonia; in the liquid into which the negative pole dipped, a resinous substance was deposited, and the solution decanted therefrom and distilled with potash, yielded ammonia and oily drops of chinoline. (Babo, J. pr. Chem. lxxii. 73.)

Nitrate of β-cinchonine crystallises slowly, by spontaneous evaporation, in monoclinic or triclinic crystals, which are moderately soluble in water and alcohol, and do not effloresce. (Schwabe.)

OXALATES OF CINCHONINE.—The *neutral oxalate* is a white precipitate, insoluble in cold, slightly soluble in boiling water, very soluble in alcohol, especially if hot, and in oxalate of ammonium. The *acid oxalate* is much more soluble than the neutral salt. *Oxalate of β-cinchonine* is crystallisable. (Schwabe.)

OXALURATE OF CINCHONINE.—Obtained by saturating a boiling solution of parabanic acid with excess of cinchonine. The solution dries up to a yellowish transparent mass, which whitens a little as it assumes the crystalline form. When boiled with hydrochloric acid, it dissolves, producing oxalic acid. (Elderhorst.)

PERCHLORATE OF CINCHONINE, $C^{20}H^{24}N^2O.HClO^4 + aq.$—Obtained by decomposing sulphate of cinchonine with perchlorate of barium. Large rhomboïdal prisms, having a strong lustre, and exhibiting a fine blue and yellow dichroïsm, even in very dilute solutions. Very soluble in water and alcohol. Melts and gives off its water at 160° C. and decomposes with explosion at a higher temperature. The salt dried at 30° C. gives off 3·57 per cent. water at 160° (Boedeker, jun. Ann. Ch. Pharm. lxxi. 59). According to Dauber (*ibid.* 66), the crystals belong to the diclinic system of Naumann (see CRYSTALLOGRAPHY), being rhomboïdal prisms of 125° 47′ and 54° 13′ with perpendicular truncation of the acute edges.

Periodate of Cinchonine.—Very unstable prisms, obtained like the perchlorate. According to Langlois, periodic acid oxidises cinchonine more rapidly than quinine.

Phosphate of Cinchonine.—Very soluble. A solution of cinchonine in phosphoric acid, yields by evaporation, sometimes rudimentary crystals, but more generally amorphous, transparent plates, which gradually become crystalline by contact with water.

Phosphate of β-cinchonine forms crystals nearly a line in length, and apparently oblique-angled. (Schwabe.)

Picrate of Cinchonine.—Yellow pulverulent precipitate, nearly insoluble in water, very soluble in alcohol.

Quinate of Cinchonine.—A strong aqueous solution of cinchonine in quinic acid deposits, when left at rest, sometimes silky needles, sometimes a mammellated mass of small granules. The salt dissolves in half its weight of water at 25° C.: it contains water of crystallisation. From a solution in warm alcohol, it crystallises on cooling in colourless, shining, short, compressed prisms, apparently unalterable either by exposure to the air or by a moderate heat, but becoming completely opaque in course of time. Water dissolves them very readily, but with partial decomposition. Their aqueous solution turns reddened litmus blue, but the alcoholic liquid from which they were deposited, turns blue litmus red.

Sulphates of Cinchonine.—The *neutral sulphate*, $2C^{20}H^{24}N^{2}O.H^{2}SO^{4} + 2\,aq.$, is obtained by exactly saturating cinchonine with dilute sulphuric acid. It forms rhombic prisms of 83° and 97°, generally very short, and having their ends truncated or bevelled: cleavable parallel to the prismatic faces; sometimes hemitropic. They are hard, transparent, and have a vitreous lustre; permanent in the air; melt a little above 100° C. and give off their 2 at. water between 100° and 120°. They dissolve at mean temperatures in 54 pts. water, 6½ pts. alcohol of specific gravity 0·85, and 11½ pts. absolute alcohol; insoluble in ether (Baup). It is but slightly decomposed by the electric current.

Sulphate of cinchonine becomes phosphorescent at 100° C. like sulphate of quinine. At higher temperatures, it melts and then decomposes, yielding a resinous matter of a fine red colour. But if the salt be previously mixed with a little water and sulphuric acid, it remains liquid at a low temperature, even after all the water has been driven off; and if kept in this state for three or four hours at 120° to 130° C. it is completely transformed into sulphate of cinchonicine, only a very small quantity of colouring matter being then produced. (Pasteur, p. 969.)

Sulphate of β-cinchonine, $2C^{20}H^{24}N^{2}O.H^{2}SO^{4} + 2\,aq.$—Crystallises in rhombic combinations $\infty P . \infty \breve{P} \infty . o P$, in which $\infty P : \infty P = 136°$. It dissolves in 75 pts. of cold, and 14 pts. of hot water; in 13·6 pts. of cold, and 1·5 pts. hot alcohol of 80 per cent., and is insoluble in ether. The dilute aqueous solution is strongly iridiscent. (Schwabe.)

Acid Sulphate of Cinchonine, $C^{20}H^{24}N^{2}O.H^{2}SO^{4} + 3\,aq.$—By adding sulphuric acid to the neutral sulphate, and evaporating till a slight pellicle is formed, the acid salt is obtained in rhombic octahedrons, often having some of their edges or summits modified, and cleaving very easily, at right angles to the axis, in well-defined shining laminæ. It is permanent in the air at ordinary temperatures, but effloresces in very dry air or if slightly warmed. When heated, it gives off 11·73 per cent. water = 3 at. At 14° C., 100 pts. of the salt [?anhydrous or hydrated], dissolve in 45 pts. water, in 90 pts. of alcohol, of specific gravity 0·85, and in 100 pts. of absolute alcohol: it is insoluble in ether. (Baup, Ann. Ch. Phys. [3] xxvii. 323.)

Sulphocyanate of Cinchonine, $C^{20}H^{24}N^{2}O.HCyS$, crystallises in brilliant anhydrous needles (Dollfus). *Sulphocyanate of β-cinchonine* is also crystallisable. (Schwabe.)

Tartrates of Cinchonine. (Pasteur, Ann. Ch. Phys. [3] xxxviii. 456, 469.—Arppe, J. pr. Chem. liii. 331.)—These salts, neutral and acid, dextro- or lævo-rotatory, are prepared by dissolving cinchonine in the proper proportions in the two modifications of tartaric acid.

α. *Neutral*, $2C^{20}H^{24}N^{2}O.C^{4}H^{6}O^{6} + 2\,aq.$—Large needles grouped in bundles, sparingly soluble in water, and giving off their crystallisation-water, 4·6 per cent., between 100° and 120° C. (Arppe.)

β. *Acid Tartrates.*—The *dextro-rotatory salt*, $C^{20}H^{24}N^{2}O.C^{4}H^{6}O^{6} + 4\,aq.$, forms nacreous shining crystals grouped in radiate stars. They belong to the trimetric system, and are often hemihedral. Observed combination, $\infty P . \breve{P} \infty . P$. Inclination of faces, $\infty P : \infty P = 133° 20'$ (nearly); $\breve{P} \infty : \breve{P} \infty = 127° 40'$; $\frac{P}{2} : \breve{P} \infty = 151° 13'$. The faces ∞P are longitudinally striated. It gives off its water (13·75 – 14·0 per cent.: calculation, 13·58 per cent.) at 100° C., and at 120°, assumes a red colour and begins to melt. It dissolves but sparingly in cold, much more easily in hot water, still more in alcohol; the solution is neutral to test-paper.

A solution containing twice the quantity of tartaric acid required to form this salt, deposits at first, another acid tartrate in transparent well-defined crystals.

Lævo-rotatory acid tartrate, $C^{20}H^{24}N^2O.C^4H^6O^6 + aq.$—This salt gives off its water = 4·58 per cent. (calc. 3·78), at 100° C. It is very sparingly soluble in alcohol and in water; the alcoholic solution is neutral, the aqueous solution acid to test-paper.

If a great excess of acid is used in the preparation, another acid tartrate is obtained crystallised in brilliant tufts, composed of very slender needles, and very different in appearance from the second dextro-rotatory acid tartrate above-mentioned. (Pasteur.)

Urate of Cinchonine, $C^{20}H^{24}N^2O.C^5H^4N^4O^3 + 4\ aq.$—Obtained by boiling uric acid with cinchonine recently precipitated and diffused through a large quantity of water. The liquid filtered at the boiling heat, deposits long prisms sparingly soluble in water, boiling alcohol, and ether. On heating the salt to 100° C. or leaving it to evaporate over oil of vitriol, it becomes opaque, and finally assumes a sulphur-yellow colour, giving off 12·49 per cent. (calc. 4 at. = 13·73 per cent.). During the desiccation, it is in a state of constant agitation, and is finally converted into a crystalline powder, probably differing in form from the hydrated crystals. (Elderhorst, *loc. cit.*)

Brominated, Chlorinated, and Iodated Derivatives of Cinchonine.

Bromocinchonine, $C^{20}H^{23}BrN^2O$. (Laurent, Ann. Ch. Phys. [3] xxiv. 302.)—When bromine is poured upon moist acid hydrochlorate of cinchonine, a product is obtained, which, when freed from excess of bromine by washing with a little alcohol, is a mixture of acid hydrobromate or hydrochlorate of bromocinchonine and sesquibromocinchonine. On treating it with boiling alcohol, the former of these salts dissolves, while the latter is nearly insoluble; and on adding ammonia to the decanted solution, boiling to expel part of the alcohol, and leaving it to cool, bromocinchonine is deposited in laminæ, which may be purified by recrystallisation.

The *acid hydrochlorate*, $C^{20}H^{23}BrN^2O.2HCl$, crystallises in the same form as the corresponding salt of cinchonine. The *chloroplatinate*, $C^{20}H^{23}BrN^2O.2(HCl.PtCl^2)$, is a pale yellow powder, containing at 50° C. 24·2 per cent. platinum (calc. 24·75).

Sesquibromocinchonine, $C^{20}H^{22\cdot5}Br^{1\cdot5}N^2O$. (Laurent, *loc. cit.*)—When the pulverulent residue, insoluble in boiling alcohol, obtained in the preparation just described, is boiled with water, and ammonia added, a white bulky precipitate of sesquibromocinchonine is formed, which, after washing and drying, dissolves in boiling alcohol, and crystallises therefrom in slender needles. It is slightly bitter; its alcoholic solution turns reddened litmus blue. It melts when heated, afterwards blackens with intumescence. It gives by analysis 55·45 per cent. C, 5·18 H, and 28·3 Br, the formula requiring 56·27 C, 5·27 H, and 28·13 Br.

The *acid hydrochlorate*, $C^{20}H^{22\cdot5}Br^{1\cdot5}N^2O.2HCl$, forms rhombic tables, in which $\infty P : \infty P = 107°$ to 108°.

The *hydrobromochlorate*, $C^{20}H^{22\cdot5}Br^{1\cdot5}N^2O.HCl.HBr$, is obtained by pouring bromine on hydrochlorate of cinchonine; boiling with alcohol as above, to remove hydrochlorate of bromocinchonine; again pouring alcohol on the residual salt; boiling; adding ammonia, which dissolves it immediately; then adding excess of hydrochloric acid to the solution, and leaving it to cool. The salt is then deposited in small rhombic tables, in which $\infty P : \infty P = 107°$ to 108°.

The *choroplatinate*, $C^{20}H^{22\cdot5}Br^{1\cdot5}N^2O.2(HCl.PtCl^2)$, is a very pale-yellow precipitate, containing at 100° C. 23·0 per cent. platinum; by calculation, 23·5.

Dibromocinchonine, $C^{20}H^{22}Br^2N^2O$. (Laurent, Compt. chim. 1849, p. 311.)—Bromine in excess is poured on acid hydrochlorate of cinchonine, to which a little water has been added; the product is heated when the action is over, to complete the bromination of the cinchonine, and expel excess of bromine; water is then poured upon it; the liquid is boiled and filtered; alcohol is added to the aqueous filtrate, heat again applied, and the solution is neutralised with ammonia. On cooling, it deposits dibromocinchonine in colourless laminæ, with nacreous reflexion.

Dibromocinchonine is insoluble in water, sparingly soluble in boiling alcohol. At about 200° C. it swells, blackens, and yields a substance which dissolves easily in potash, and is separated therefrom by acids in brown flakes. Dibromocinchonine gives by analysis 51·20 per cent. C, 4·4 H, and 34·00 Br, the formula requiring 51·28 C, 4·70 H, and 34·19 Br. A solution which had been left for some days in an open vessel, deposited rectangular octahedrons, containing 4·2 per cent. = 1 at. water of crystallisation.

The *acid hydrochlorate*, $C^{20}H^{22}Br^2N^2O.2HCl$, obtained by treating the base with hydrochloric acid, is sparingly soluble in water, and separates from a boiling solution on cooling, in rhombic tablets, having their four acute angles truncated; $\infty P : \infty P =$

104° to 105° : $\breve{P}\infty : oP = 137$. Its solution deflects the plane of polarisation to the right.

DICHLOROCINCHONINE, $C^{20}H^{22}Cl^2N^2O$. (Laurent, Ann. Ch. Phys. [3] xxiv. 302.)—The acid hydrochlorate of this base is formed by passing chlorine into a hot concentrated solution of acid hydrochlorate of cinchonine; and on adding ammonia to a solution of this salt in boiling water, the base is precipitated as a light flocculent mass, which crystallises from boiling alcohol in microscopic needles, yielding by analysis 18·9 per cent. chlorine (calc. 18·83).

The *acid hydrochlorate*, $C^{20}H^{22}Cl^2N^2O.2HCl$, is sparingly soluble in water, and requires 50 pts. of alcohol to dissolve it: the solution is dextro-rotatory. The salt crystallises in rhombic tables isomorphous with the crystals of acid hydrochlorate of cinchonine, $\infty P : \infty P = 106°$; $P\infty : oP = 136° 30'$ to $137° 30'$.

The *chloroplatinate*, $C^{20}H^{22}Cl^2N^2O.2(HCl.PtCl^2)$, is a pale yellow powder, yielding at 100°, 25·00 per cent. platinum (calc. 25·06).

The *acid hydrobromate*, $C^{20}H^{22}Cl^2N^2O.2HBr$, obtained by treating the base with hydrobromic acid, is sparingly soluble, and crystallises in brilliant laminæ, having sensibly the same angles as those of the acid hydrochlorate, but presenting a different appearance, inasmuch as the modifying faces are considerably developed, so that the rhombic tablet is transformed into a six-sided prism; $\infty P : \infty \breve{P} = 104°$; $\breve{P}\infty : oP = 137°$. The salt has the same composition as the acid hydrochlorate of dibromocinchonine, but differs from it in giving with nitrate of silver a precipitate of bromide of silver, whereas the latter yields a precipitate of chloride.

The *nitrate* is sparingly soluble in water, and crystallises in small elongated tetrahedrons, formed of four equal scalene triangles, and having their opposite edges truncated.

IODOCINCHONINE, $2C^{20}H^{24}N^2O.I^3$ (?) (Pelletier, Ann. Ch. Phys. [2] lxiii. 181.)—When cinchonine is triturated with about half its weight of iodine, and the product is treated with alcohol of 36 per cent., the whole dissolves, and on leaving the solution to evaporate, it first deposits the so-called iodocinchonine in saffron-coloured plates, afterwards crystalline nodules of hydriodate of cinchonine. On treating the whole with boiling water, the hydriodate dissolves, and the iodocinchonine separates in the melted state.

Iodocinchonine has a deep saffron-yellow colour when seen in mass; its powder is lighter. It has a slightly bitter taste. When heated, it softens at 25° C. but does not enter into complete fusion till heated to 80°. It is insoluble in cold water, very soluble in boiling water, soluble in alcohol and ether. It gave by analysis 28·83 per cent. iodine (calc. 29·03).

Iodocinchonine may be decomposed by the successive action of acid and alkaline solutions. It is likewise decomposed by nitrate of silver. (Pelletier.)

If the preceding formula be correct, the compound is not iodocinchonine, but iodide of cinchonine.

Sulphate of Iodocinchonine. (W. B. Herapath, Chem. Soc. Qu. J. xi. 151.)—Cinchonine treated with iodine and strong sulphuric acid, yields a crystalline salt, which resembles the corresponding quinine-compound in its action on light. It crystallises in long needles, which appear deep purple-red by transmitted, and dark purple-blue by reflected light; their laminæ appear lemon-yellow by transmitted light, and if two such thin plates be superposed in such a manner that their longest dimensions may cross one another at right angles, the system is perfectly impervious to light, the two plates acting in fact like two tourmalines with their axes crossed. (For further details relating to these properties, see SULPHATE OF IODOQUININE, under QUININE). The salt dissolves easily in strong boiling alcohol, and crystallises therefrom; sparingly in weak alcohol, and scarcely at all in water, ether, and chloroform. Herapath assigns to it the formula $C^{30}H^{36}N^4O^2I^6.H^2SO^4 + 3aq.$, which is very improbable.

Sulphate of Iodo-β-cinchonine is obtained in indistinct crystals on adding a warm solution of 3 pts. iodine in 115 pts. alcohol to a solution of 10 pts. of sulphate of β-cinchonine in 144 pts. acetic acid, and 12 pts. dilute sulphuric acid. (Schwabe.)

Derivatives of Cinchonine containing Organic Radicles.

BENZOYL-CINCHONINE, $C^{27}H^{28}N^2O = C^{20}H^{23}(C^7H^5O)N^2O$. (Schützenberger, Ann. Ch. Pharm. cviii. 351.)—Dry cinchonine dissolves with rise of temperature in chloride of benzoyl, and the mixture, if heated for a few seconds, solidifies to a crystalline mass of hydrochlorate of benzoyl-cinchonine. This salt dissolves readily in water, and the solution, quickly decanted from undissolved chloride of benzoyl, yields with ammonia a white glutinous precipitate of benzoyl-cinchonine, which hardens in the cold. It is tasteless and uncrystallisable, insoluble in water, but dissolves in all proportions in alcohol and ether. Its salts are easily soluble in water. The *hydrochlorate* is $C^{27}H^{30}N^2O.HCl$; the *chloroplatinate* $C^{27}H^{30}N^2O^2. 2(HCl.PtCl^2)$.

METHYL-CINCHONINE, $C^{21}H^{26}N^2O = C^{20}H^{23}(CH^3)N^2O$. (Stahlschmidt, Ann. Ch. Pharm. xc. 218.)—The *hydriodate* of this base, $C^{21}H^{26}N^2O.HI$, is produced by the action of iodide of methyl on pulverised cinchonine. It dissolves easily in boiling water, and separates in fine needles on cooling. It is not attacked by iodide of methyl when heated therewith to 100° C. in a sealed tube: hence cinchonine appears to contain but 1 at. of hydrogen replaceable by an alcohol-radicle.

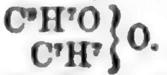
The iodide treated with oxide of silver, yields a solution of the base, which, when quickly evaporated over the water-bath, leaves a brown crystalline mass, from which, when dissolved in water, brown oily drops separate. The aqueous solution precipitates the salts of sesquioxides.

The salts of methyl-cinchonine are very soluble in water and in alcohol, and difficult to crystallise.

The *chloroplatinate*, $C^{21}H^{26}N^2O.2(HCl.PtCl^2)$, yields when dried at 100°C., 26·70 — 26·77 per cent. platinum, the formula requiring 26·93.

CINCHOVATINE. Syn. with ARICINE (p. 357).

CINNABAR. Protosulphide of mercury. (See MERCURY.)



CINNAMEIN. *Cinnamate of Benzyl.* $C^{16}H^{14}O^2 = \left.\begin{matrix} C^9H^7O \\ C^7H^7 \end{matrix}\right\}O$. (Plantamour, Ann. Ch. Pharm. xxvii. 329; xxx. 241.—Frémy, Ann. Ch. Phys. lxx. 189.—H. Deville, Ann. Ch. Pharm. lxxiv. 230.—E. Kopp, Compt. chim. 1850, p. 410.—Scharling, Ann. Ch. Pharm. xcvii. 184.—Gm. xiii. 283.—Gerh. iii. 404.)—This compound was discovered by Plantamour (1838), who obtained it from balsam of Peru, in which, according to Simon, it exists ready formed; according to Frémy and Deville, it exists also in small quantity in Tolu balsam. According to Scharling, cinnamic acid dissolved in peruvin (a mixture of benzylic alcohol and toluene) forms a liquid, which, when saturated with hydrochloric acid, yields to boiling water a neutral oil resembling cinnamein.

Preparation.—Balsam of Peru is saponified by agitation with excess of caustic potash, and the solid soap dissolved in water: the solution on being warmed, separates after a few minutes into two layers, and the upper, which is oily, is to be repeatedly washed with water, till the oil exhibits a faint reddish-yellow colour. The residual water is evaporated over the water-bath; the oil dissolved in warm alcohol and evaporated; and this treatment repeated as long as resin separates out on evaporation. (Plantamour).—2. Balsam of Peru dissolved in alcohol of 36°, is treated with alcoholic potash, whereby a compound of resin with potash is precipitated; the solution is mixed with water; the cinnamein which separates out in the form of an oil is separated from the inferior solution of cinnamate of potassium, and dissolved in freshly-rectified rock-oil, whereby resin is removed; the rock-oil is then evaporated, and the residual oil placed in a vacuum. Cinnamein thus prepared, still retains styracin in solution, the quantity varying according to the nature of the balsam. To free it from this impurity, it is dissolved in weak alcohol, and cooled for several days below 0°, as long as a crystalline deposit of styracin continues to form (Frémy).—3. Balsam of Peru is repeatedly boiled with aqueous carbonate of sodium, and the cinnamate of sodium is removed by washing, the residue then separating into a resin, and a yellowish-brown liquid which must be heated to 170° C. on the oil-bath, and distilled in steam heated to 170°. Colourless, somewhat milky cinnamein then passes over, and is freed from adhering water by standing for some time in a warm place, over chloride of calcium. Sometimes, perhaps always, the cinnamein thus prepared contains in solution styracin, which, after long standing, partially crystallises out (Scharling). Calcined magnesia or oxide of lead also separates cinnamein from balsam of Peru, by combining with the cinnamic acid, and separating resin. (Simon.)

Properties.—Cinnamein is a feebly coloured or colourless, strongly refracting neutral oil, which remains liquid when cooled to −12° or −15° C. for several days. It boils at 305°, and distils without decomposition (Plantamour); between 340° and 350°, with partial decomposition (Deville, Frémy). It has a feeble pleasant odour. Its taste is sharp and aromatic, recalling that of fat. It makes grease spots on paper. Specific gravity, 1·098 at 14°; 1·0925 at 25° (Scharling). It is nearly insoluble in water, but dissolves in alcohol and ether.

Cinnamein contains, according to Scharling's analysis, 79·18 to 79·24 per cent. C, 6·56 to 6·03 H, and 14·26 to 13·72 O, agreeing nearly with the preceding formula, which requires 80·62 C, 5·88 H, and 13·45 O.—When kept under water for some time, it yields a crystalline substance of the same composition, metacinnamein, which melts between 12 and 15° C. sometimes resolidifies after cooling and standing, but after solution in boiling alcohol cannot again be obtained in the crystalline form. (Scharling.)

Cinnamein slowly absorbs moist *oxygen* (**Frémy**). When exposed for years to *air* and *light*, it acquires a rancid odour and acid reaction. Crystallised cinnamein preserved in a glass vessel for a year melted to a viscous mass, and in another year solidified to a transparent amorphous mass (**Scharling**). Cinnamein is partially decomposed by distillation, leaving a small quantity of tar, and yielding a distillate differing in composition from the original substance.

It is resinised by strong *sulphuric acid* (**Frémy**. It slowly absorbs *chlorine*, more easily when heated, becoming at the same time coloured and thickened, and when distilled, ultimately yields chloride of benzoyl together with an oil (**Frémy**). *Nitric acid* acts briskly on cinnamein when heated, forming a yellow resin and a large quantity of bitter almond oil. *Peroxide of lead* acts in a similar manner (**Frémy**). Cinnamein forms a crystalline compound with *ammonia* (**Plantamour**). Mixed with *sulphide of carbon* and powdered hydrate of potassium, it forms a saline mass containing xanthate of potassium (**Scharling**). Rapidly heated with very concentrated *potash-ley*, or melted with hydrate of potash, it gives off hydrogen, and passes into cinnamate (and benzoate) of potassium (**Frémy**). Treated with very concentrated potash-ley in the cold, or with alcoholic potash, it is completely resolved, in 24 hours, without disengagement of gas or absorption of oxygen, into benzylic alcohol and cinnamate of potassium: $C^{16}H^{14}O^2 + KHO = C^7H^8O + C^9H^7KO^2$. By the continued action of the potash, the benzylic alcohol may be converted into benzylene. (C^7H^6.)

Plantamour, by treating cinnamein with strong alcoholic potash, obtained, together with cinnamic acid, an acid which he designated as *carbobenzoic* or *myroxylic acid;* probably impure benzoic-acid resulting from the decomposition of cinnamic acid under the influence of potash (p. 984).

CINNAMENE. C^8H^8. *Cinnamol. Styrol. Volatile Oil of Liquid Storax.* (**Bonastre**, J. Pharm. xvii. 338.—**D'Arcet**, Ann. Ch. Phys. lxvi. 110.—**Mulder**, J. pr. Chem. xv. 307.—**E. Simon**, Ann. Ch. Pharm. xxxi. 265.—**C. Herzog**, Pharm. Centr. 1839, p. 833.—**Gerhardt and Cahours**, Ann. Ch. Phys. [3] i. 96.—**E. Kopp**, Compt. chim. 1846, p. 87; further, Compt. rend. liii. 634.—**Blyth and Hofmann**, Ann. Ch. Pharm. liii. 293, 325.—**Hempels**, *ibid.* lix. 316.—**Scharling**, *ibid.* xcvii. 184.—**D. Howard**, Chem. Soc. Qu. J. xiii. 134; **Gm.** xiii. 1; **Gerh.** iii. 374.)—This compound is produced by the decomposition of cinnamic acid (p. 981), and is contained in liquid storax (p. 982), whence it may be obtained by distillation with water. It was formerly supposed that cinnamene obtained from cinnamic acid was not identical, but only isomeric, with styrol, the volatile oil of storax, because the latter is completely converted by heat into a solid substance, *metastyrol*, of the same composition, whereas with cinnamene this change had been observed to take place but imperfectly; but E. Kopp has lately shown that this transformation takes place quite as completely with cinnamene as with styrol, an observation which removes the only objection to the supposed identity of the two substances.

Preparation.—a. *From Cinnamic Acid and the Cinnamates.* Cinnamic acid, when slowly distilled at its boiling point, is completely resolved into cinnamene and carbonic anhydride:

$$C^9H^8O^2 = CO^2 + C^8H^8.$$

Pure cinnamate of calcium is likewise resolved by dry distillation into cinnamene and carbonate of calcium (**D. Howard**). Cinnamic acid distilled with excess of lime or baryta yields a mixture of cinnamene and benzene, which may be separated by rectification.

b. *From Storax.*—The liquid balsam is distilled in a copper still connected with a worm-tub, with water containing carbonate of sodium, to retain cinnamic acid; 3½ lbs. of carbonate of sodium suffice for 10 lbs. of storax. The water which passes over is milky, and the cinnamene floats on the surface. The quantity obtained varies with the age of the balsam. Blyth and Hofmann obtained in one operation about 360 grammes of oil from 20½ kil. of liquid storax, in another not more than 90 grms. from 13½ kil. The oily distillate is dried over chloride of calcium and rectified. This last operation requires particular precautions. The liquid begins to give off vapour between 100° and 120° C., and at 145° it is in full ebullition, a limpid oil then passing over, and the thermometer remaining stationary for some time; suddenly, however, a considerable rise takes place, and the thermometer must then be quickly withdrawn from the retort, for the residue thickens, and on cooling solidifies to a transparent glass, consisting of metacinnamene or metastyrol. The quantity of this solid residue varies, but it sometimes amounts to half the oil subjected to distillation.

c. Cinnamene may also be obtained from the resin of Peru balsam, by heating that substance mixed with pumice to dull redness in a retort, and subjecting the oil which passes over, together with benzoic acid and an aqueous liquid, to fractional distillation. The portion which goes over under 175° C., and is lighter than water, is collected, repeatedly distilled with potash-solution, allowed to stand several days over pieces of solid potash, and then distilled at a temperature not exceeding 150° C. The distillate is dried with chloride of calcium, treated with potassium, whereby hydrogen is evolved, and the fluid part is decanted from the resulting gelatinous precipitate and distilled. The boiling point then gradually rises to 100°—140° C., by which time all the cinnamene remains behind, amounting to $\frac{3}{8}$ of the liquid employed. (Scharling, Ann. Ch. Pharm. xcvii. 184.)

Cinnamene is a very mobile colourless oil, having a strong persistent aromatic odour, reminding of benzene and naphthalene together. It does not solidify at −20° C. It is very volatile, the grease spots which it produces on paper disappearing in a few seconds. Specific gravity 0·924. Boiling point 145·75° C. (Blyth and Hofmann); 145° (E. Kopp). It is neutral, mixes in all proportions with alcohol and ether, volatile oils, and sulphide of carbon, and dissolves sulphur and phosphorus.

Cinnamene is not acted upon by *potash.* With *fuming sulphuric acid* it appears to form a conjugated acid. If added by drops to *fuming nitric acid,* it dissolves with evolution of red vapours; and water added to the solution throws down a yellow resin, which, by careful distillation, yields crystals of nitrocinnamene. If boiled with excess of nitric acid, it yields benzoic or nitrobenzoic acid, according to the strength of the nitric acid. Distilled with dilute *chromic acid,* it yields crystals of benzoic acid With *chlorine* and *bromine,* it forms chloride and bromide of cinnamene.

Metacinnamene. *Metastyrol. Draconyl.*—This is the solid substance into which cinnamene or styrol is converted by the action of heat. The conversion takes place readily in a sealed tube heated to 200° C. in an oil-bath. Metacinnamene is likewise obtained from dragon's blood. When the crude oil produced by the dry distillation of that substance is distilled till the temperature rises to 280° C. a liquid is obtained containing toluene (hydride of benzyl, p. 573), and cinnamene. On distilling this mixture at a temperature below the boiling point, till the greater part of the toluene has passed over, a viscous liquid remains, consisting of metacinnamene, held in solution by a small quantity of styrol. On pouring this liquid into alcohol, the cinnamene dissolves, while the metacinnamene is precipitated in the form of a soft colourless resin like turpentine, which may be washed with alcohol, and then dried in a stove at 150° C.

According to E. Kopp, the transformation of cinnamene into metacinnamene likewise takes place spontaneously at ordinary temperatures. This property, joined to the high refracting power of metacinnamene, suggests the possibility of using cinnamene for filling hollow glass lenses or prisms. According to Kovalevsky (Ann. Ch. Pharm. cxx. 66), metacinnamene exists also, together with cinnamene, in liquid storax.

Metacinnamene is a colourless, limpid, highly refractive substance, destitute of taste and odour. At mean temperatures it is hard, and may be cut with a knife; but it softens by heat, and may then be drawn out into long threads. It is insoluble in water and alcohol; ether dissolves it in small quantity, and at the boiling heat transforms it into a gelatinous mass, which, after drying at 100° C., forms a white spongy substance, having exactly the composition of styrol.

Metacinnamene liquefies when heated in a small retort, and yields by distillation pure cinnamene, which may be reconverted into metacinnamene by heating to 200° C. in a sealed tube.

Chlorine and *bromine* act very slowly on metacinnamene, but ultimately convert it into chloride and bromide of cinnamene respectively. Strong *sulphuric* acid carbonises it. By fusion with *hydrate of potassium* it is converted into styrol. *Nitric acid* of ordinary strength acts but slightly on metacinnamene, but fuming nitric acid dissolves it easily, with evolution of red vapours; and if the acid has been added in sufficient quantity, the solution yields with water a precipitate of nitrometacinnamene.

Compounds and Derivatives of Cinnamene.

Bromide of Cinnamene. $C^8H^8Br^2$.—Produced by the action of bromine on cinnamene. It is insoluble in water, but very soluble in alcohol and ether, whence it crystallises in needles. Solutions saturated at the boiling heat usually deposit it in the form of an oil, which remains liquid for a long time, and solidifies suddenly when agitated. It has a peculiar odour, which is not disagreeable, but excites tears. It melts at 67° C., and often remains liquid, even when cooled to 30° C., but the least agitation causes it to solidify in a crystalline mass. Its boiling point is above 200° C. It may be distilled almost wholly without alteration. Alcoholic potash converts it into bromide of potassium and a brominated organic compound.

Chloride of Cinnamene.—$C^8H^8Cl^2$. Oily liquid, produced by the action of chlorine on cinnamene. It is decomposed by distillation into hydrochloric acid and another oily compound.

Treated with alcoholic potash, it yields chlorocinnamene, C^8H^7Cl.

Trichloride of Dichlorocinnamene, $C^8H^6Cl^2.3Cl^2$, is obtained, according to Laurent, by the action of chlorine on cinnamene.

Nitrocinnamene. *Nitrostyrol.* $C^8H^7(NO^2)$.—Produced by the action of fuming nitric acid on cinnamene (p. 980). It crystallises in large prisms; has an odour of cinnamon which excites tears; produces painful blisters on the skin.

Nitrometacinnamene. Nitrometastyrol. Nitrodraconyl.—This compound, isomeric with the last, is precipitated on adding water to the product of the action of fuming nitric acid on metacinnamene. It is a white amorphous powder, insoluble in water, acids, potash, ether, and alcohol. When slightly heated, it burns with explosion. When distilled with lime, it is decomposed, with separation of carbon and evolution of ammonia, together with a small quantity of a brown oil containing phenylamine. It does not appear to be attacked by strong nitric acid, even after several hours' boiling.

CINNAMIC ACID. $C^9H^8O^2 = \left.\begin{matrix}C^9H^7O \\ H\end{matrix}\right\}O$. *Zimmtsäure. Cinnamylsäure.* (Dumas and Péligot [1834], Ann. Ch. Phys. lvii. 311.—E. Simon, Ann. Ch. Pharm. xxxi. 265.—Stenhouse, *ibid.* lv. 1; lvii. 79.—Herzog, Arch. Pharm. xvii. 72; xx. 159.—E. Kopp, Compt. chim. 1847, p. 198; 1849, p. 146; 1850, p. 140.—Cahours, Ann. Ch. Phys. [3] xxiii. 341.—Schabus, Wien Akad. Ber. 1850 [2] 206.—Chiozza, Ann. Ch. Phys. [3] xxxix. 439.—J. Löwe, J. pr. Chem. lxv. 188.—Piria, Ann. Ch. Pharm. c. 104.—Bertagnini, Cimento, iv. 46.—Gm. xiii. 268.—Gerh. iii. 388.)—This acid exists in the free state in several balsams, as in liquid storax, Tolu balsam, Peru balsam, and gum benzoin, and is often deposited in large prismatic crystals from old samples of oil of cinnamon; also from cinnamon-water.

Formation.—Cinnamic acid is produced: 1. By the action of oxidising agents on cinnamic aldehyde and on styrone.—2. By heating bitter-almond oil with chloride of acetyl in a sealed tube to 120°—130° C., but not higher, for 20—24 hours, hydrochloric acid being formed at the same time:

$$C^7H^6O + C^2H^3O.Cl = HCl + C^9H^8O^2.$$

The cinnamic acid may be extracted from the viscid residue by digestion with water containing ammonia.—3. By boiling cinnamein with potash, benzylic alcohol being formed at the same time (p. 979).—4. By fusing styracin with potash (Frémy) or boiling it with potash-ley. (Simon.)

Preparation.—*a.* From the deposit of cinnamate of lead mixed with cinnamic acid, found in the old leaden packages in which oil of cassia-cinnamon is imported. The deposit is dissolved in alcohol and filtered from the cinnamate of lead, and the alcohol is removed from the filtrate by distillation; the cinnamic acid then quickly crystallises out from the oil, and is purified by treatment with carbonate of sodium and precipitation. The residual cinnamate of lead is boiled with carbonate of sodium, filtered from the carbonate of lead, and the cinnamic acid is precipitated by dilute sulphuric acid, in silvery lustrous laminæ, which are washed, and recrystallised from alcohol (Herzog). Dumas and Péligot dissolve the crystalline deposit from oil of cinnamon in boiling water, and evaporate the filtrate to the crystallising point.

b. From Liquid Storax.—Liquid storax is distilled with water and $\frac{1}{2}$ to $\frac{7}{10}$ pts. of crystallised carbonate of sodium, whereupon styrol passes over. The residual aqueous liquid is filtered from the resin; and the filtrate is mixed at first with just so much sulphuric acid, that a very small quantity of cinnamic acid is precipitated along with dissolved resin; and the liquid filtered from this precipitate is treated with excess of sulphuric acid, which precipitates cinnamic acid of a tolerably white colour. It is dissolved in a large quantity of water, with as little carbonate of sodium as possible, and again precipitated, first with a little sulphuric acid, and then, after the filtration, with an excess of acid, by which a white precipitate is formed. This is washed with water, dried, and dissolved in alcohol, which, by spontaneous evaporation, yields quite white and very large crystals (E. Simon). Erdmann and Marchand purify the acid by distillation, pressure between paper moistened with alcohol, and repeated crystallisation. D. Howard (Chem. Soc. Qu. J. xiii. 72) finds that cinnamic acid prepared from liquid storax contains a small quantity of benzoic acid, from which, however, it is purified by crystallisation from alcohol.

c. From Balsam of Peru.—When the slimy residue which deposits in Peruvian balsam by keeping, is dissolved in warm alcohol, and the filtrate is placed in a tall and narrow cylinder with a layer of water on the top, crystals of nearly pure cinnamic acid separate in a few days from the clear brown liquid (Herberger). When Peruvian balsam is boiled with thick milk of lime, the liquid filtered, the residual magma exhausted three or four times with boiling water, and the solution again filtered, the filtrate deposits on cooling, loose, almost white masses of crystals; and these, when decomposed by hydrochloric acid, yield nearly pure cinnamic acid, which may be obtained perfectly pure, either by distillation, or by solution in ammonia, filtration, and precipitation while hot by hydrochloric acid (E. Kopp). Simon proceeds as with storax.

d. From Balsam of Tolu.—Balsam of Tolu is boiled six or seven times with solutions of carbonate of sodium, which are taken continually weaker (the last extracts only contain a little benzoic acid, produced by the action of the alkali on the resin); and the alkaline decoctions are strongly concentrated by evaporation, and precipitated hot by hydrochloric acid, whereupon most of the cinnamic acid melts into a brown resin, and but little crystallises out on cooling. The latter is pressed, the resin is pulverised, and both are dissolved in ammonia diluted with 2 pts. of water, and heated to 80° C. The greater part of the resin then remains dissolved. The liquid is filtered; the residue is boiled with water; and the whole of the very brown liquids are evaporated and decomposed, while boiling, by hydrochloric acid, whereupon most of the acid again melts, while the remainder seprates out on cooling in nearly white crystalline scales, which are pressed, and washed with a little cold water. The melted acid is also washed with a little water. The whole of the acid is heated in a porcelain dish covered with paper till the water is expelled — very little acid subliming even at 200° C.—and the fused residue is bruised and distilled. Pure cinnamic acid then passes over as a colourless, clear, strongly refracting liquid, which solidifies to a white crystalline mass like stearin. Towards the end, yellowish vapours arise, which, when collected in another receiver, solidify into a mass of acid, which is contaminated by the presence of the empyreumatic oils of the resin, but may be obtained quite pure by recrystallisation from boiling water. (E. Kopp.)

Properties.—Cinnamic acid crystallises in colourless prisms or laminæ belonging to the monoclinic system. Ordinary combination, $\infty P . [\infty P \infty] . [P \infty]$. Ratio of orthodiagonal, clinodiagonal, and principal axis = 0·3674 : 1 : 1·1694. Inclination of clinodiagonal to principal axis = 82° 58′. Cleavage perfect parallel to $[\infty P \infty]$. Specific gravity of crystals = 1·195.

Cinnamic acid dissolves sparingly in cold water, easily in boiling water, alcohol, and ether; water precipitates it from the alcoholic solution. It melts at 129° C., and boils without decomposition at 293° (Dumas and Péligot), at 300°—304° (E. Kopp), with or without decomposition, according to the manner in which it is heated. If enclosed in a sealed tube, it may be heated to 200° C. (in a paraffin-bath) for several hours without alteration. (Howard.)

Decompositions.—1. Cinnamic acid, when slowly distilled, is resolved into cinnamene and carbonic anhydride: $C^9H^8O^2 = C^8H^8 + CO^2$, a small quantity of stilbene, $C^{14}H^{12}$, being likewise produced, and passing over with the cinnamene (Howard).—2. On red-hot platinum-foil, or in the flame of a candle, it burns with a smoky flame (Bizio). On red-hot charcoal, it evaporates without flame producing a strong biting smoke.—3. Strong *sulphuric acid*, or *sulphuric anhydride*, converts it into sulpho-cinnamic acid.—4. Cinnamic acid heated with excess of *iodine*, melts to a dark brown mass; and when this mass is heated with water, and the excess of iodine expelled by evaporation, iodocinnamic acid crystallises out on cooling (Herzog).—5. *Bromine* passed over cinnamate of silver forms bromocinnamic acid (Herzog).—6. *Chlorine* passed in diffused daylight over dry cinnamic acid, forms a tough greasy substance, which, when heated with carbonate of potassium, forms chlorocinnamate of potassium, and deposits a white oil containing chlorine (Herzog). The same products are formed when chlorine is passed into warm aqueous cinnamic acid or cinnamate of sodium, and when cinnamic acid is distilled with hypochlorite of calcium (Stenhouse, E. Kopp), or with chlorate of potassium and hydrochloric acid.—7. Strong *nitric acid* converts cinnamic acid into nitrobenzoic acid, provided the mixture be kept cool; otherwise nitrous fumes are evolved, and hydride of benzoyl is first obtained, then benzoic and nitrobenzoic acids. The same products are formed on heating cinnamic acid with more dilute nitric acid. —8. Boiled with *peroxide of lead* in aqueous solution, cinnamic acid gives off the odour of bitter-almond oil, while the peroxide of lead assumes a light yellow colour, and is partially converted into benzoate of lead. This behaviour serves to distinguish cinnamic acid from benzoic acid (Stenhouse).—9. Cinnamic acid distilled with *sulphuric acid* and *acid chromate of potassium*, yields oil of bitter-almonds (Simon).—10. With *pentachloride of phosphorus* (also the trichloride, according to Béchamp), it yields chloride of cinnamyl (Cahours).—11. Fused with *hydrate of potassium*, it gives off hydrogen, and forms acetate and benzoate of potassium, a small quantity of salicylate of potassium being also produced by the action of potash on the benzoic acid previously formed (Chiozza):

$$C^9H^8O^2 + 2KHO = C^2H^3KO^2 + C^7H^5KO^2 + H^2.$$

Cinnamic acid is not decomposed by boiling with strong caustic potash (Simon).—12. In the dry distillation of the alkaline cinnamates or of cinnamic acid with *caustic baryta* or *lime*, a carbonate is formed, together with cinnamene and benzene.—13. Cinnamate of calcium, distilled with *formate of calcium*, yields cinnamic aldehyde (Piria. The reactions 6, 7, and 8, serve to distinguish cinnamic acid from benzoic acid.

CINNAMATES.—Cinnamic acid is monobasic, the formula of its salts being $C^9H^7MO^2$. They are crystallisable, and bear considerable resemblance to the benzoates. The cinnamates of the alkali-metals are easily soluble in water; those of the earth-metals and heavy metals sparingly soluble, the least soluble being the silver-salt. They dissolve more readily in water containing chlorides or nitrates.

The solutions of most cinnamates yield a precipitate of cinnamic acid when decomposed by the stronger acids. Cinnamates are decomposed by dry distillation, giving off an odour of bitter-almonds. With strong *nitric* acid, they turn yellow, and give off the odour of oil of cinnamon and bitter-almond oil. They likewise yield bitter-almond oil when distilled with *chromic* acid. With *ferric* salts, they give a yellow precipitate, and with *manganous* salts, the cinnamate being in excess, a white precipitate which soon becomes yellowish and crystalline. Benzoates give a reddish precipitate with ferric salts, and none with manganous salts. The cinnamates have been investigated chiefly by Herzog (J. pr. Chem. xxix. 51), and E. Kopp (Compt. rend. liii. 634).

Cinnamate of Aluminium.—Loose white powder, sparingly soluble in cold, easily in hot water.

Cinnamate of Ammonium, $2C^9H^7(NH^4)O^2 + aq.$—Sparingly soluble in cold water: gives off ammonia when melted, yielding a crystalline sublimate and a resinous residue. With excess of cinnamic acid, it forms an acid salt still less soluble in water. (Herzog.)

Cinnamate of Antimony and Potassium is deposited from a mixture of cinnamate of potassium and tartar-emetic, in delicate hydrated crystals, which redissolve if left for a long time in the liquid. The salt yields by calcination, a colourless residue, which effervesces with acids, and is coloured orange-red by sulphuretted hydrogen. (Herzog.)

Cinnamate of Barium, $2C^9H^7BaO^2 + aq.$—Precipitate, soluble in boiling water, crystallising on cooling. Gives off its water at 110° C. (Herzog). According to E. Kopp, the salt forms broad, irregular, transparent, nacreous laminæ containing $C^9H^7BaO^2 + aq.$ becomes anhydrous at 140° C. and when distilled with excess of barytic hydrate, yields nearly pure cinnamene.

Cinnamate of Calcium, $C^9H^7BaO^2 + aq.$—Very little soluble in cold water, easily in boiling water, whence it separates in light crystalline masses (Herzog).—$2C^9H^7CaO^2 + 3aq.$ White shining needles composed of thin nacreous laminæ, having the form of nearly rectangular parallelograms. It gives off one-third of its water when exposed to the air at ordinary temperatures, and the rest at 150° C. (E. Kopp.)

Cinnamate of Cobalt.—Rose-coloured precipitate, soluble in alcohol. (Herzog.)

Cinnamate of Copper, $C^9H^7CuO^2.xCuHO$.—The greenish-blue precipitate obtained by double decomposition, is a highly hydrated basic salt. When heated, it loses its blue colour and decomposes, giving off cinammic acid and cinnamene, and leaving metallic copper mixed with charcoal.

Cinnamates of Iron.—Both the *ferric* and *ferrous* salts are yellow precipitates, sparingly soluble in water. (Herzog.)

Cinnamate of Lead, $C^9H^7PbO^2$.—Granular crystalline powder, anhydrous and insoluble in water (Herzog). Sometimes obtained in laminæ, flattened or elongated into needles, and in small hard rounded grains (E. Kopp). Alcohol extracts a portion of the cinammic acid, leaving a basic salt.

Cinnamate of Magnesium, $2C^9H^7MgO^2 + 3aq.$, crystallised in the cold, forms small white needles, which quickly become opaque on being exposed to the air. From a boiling solution it separates in tufts of shining needles, formed by the superposition of elongated laminæ, very thin, and of nacreous aspect. It melts at 200° C. and becomes anhydrous.

Manganous Cinnamate, $C^9H^7MnO^2 + aq.$—Yellowish-white crystalline precipitate, which dissolves in boiling water acidulated with acetic acid, and separates therefrom in shining yellowish laminæ, superposed on one another. (E. Kopp.)

Mercurous Cinnamate.—White curdy precipitate.

Cinnamate of Nickel.—Green precipitate soluble in alcohol.

Cinnamate of Potassium, $2C^9H^7KO^2 + aq.$—Crystals belonging to the monoclinic system, giving off their water at 120°C, and decrepitating when strongly and suddenly heated. It is very soluble in water, but less so than the benzoate; moderately soluble in alcohol (Herzog). From a rather strong boiling solution containing excess of caustic potash, it crystallises readily in nacreous needles, which are anhydrous. (E. Kopp.)

When cinnamic acid is dissolved in a hot solution of cinnamate of potassium, a sparingly soluble *acid salt* is deposited on cooling. (Herzog.)

Cinnamate of Silver, $C^9H^7AgO^2$.—White curdy precipitate, becoming crystalline after a while; not much altered by light. It is insoluble in boiling water, but dissolves slightly in the liquid from which it has been precipitated (Herzog). White precipitate, or silky nacreous needles composed of small elongated laminæ, often bifurcated. (E. Kopp.)

Cinnamate of Sodium, $2C^9H^7NaO^2 + aq.$—Crystals with dull surface, which give off their water at 110° C. (Herzog). The anhydrous salt, $C^9H^7NaO^2 + 2aq.$, crystallises in crusts surmounted with tufts of small needles, or in compact nodules. From a solution in weak caustic soda, it crystallises in beautiful needles containing ½ at. water of crystallisation. In strong caustic soda, it dissolves but sparingly at common temperatures, separating in hard, yellowish, radiated, anhydrous spheres. (E. Kopp.)

Cinnamate of Strontium, $C^9H^7SrO^2 + 2aq.$, when recently crystallised, forms white, nacreous, nearly opaque needles, composed of very small prisms. It is much more soluble in hot than in cold water; gives off 1 at. water when exposed to dry air, and the rest at 140° C. (E. Kopp.)

Cinnamate of Tin.—The *stannic* salt is a white precipitate. (Herzog.)

Cinnamate of Uranyl.—Yellow precipitate, sparingly soluble in boiling water. (Herzog.)

Cinnamate of Zinc.—Cinnamic acid dissolves zinc at the boiling heat, with evolution of hydrogen. The salt is moderately soluble, and crystallises by evaporation (Herzog),—$C^9H^7ZnO^2 + aq.$ White precipitate, which dissolves in boiling water, and crystallises therefrom in shining, transparent, prismatic needles, sometimes grouped like mushrooms. (E. Kopp.)

CINNAMIC ETHERS. *Cinnamate of Ethyl*, $C^{11}H^{12}O^2 = C^9H^7(C^2H^5)O^2$. (Herzog, Arch. Pharm. [2] xvii. 72.—Marchand, Ann. Ch. Pharm. xxxii. 270.—E. Kopp. J. pr. Pharm. [3] xi. 72.—Plantamour, Ann. Ch. Pharm. xxx. 345).—This compound is easily obtained by distilling a mixture of 4 pts. absolute alcohol, 2 pts. cinnamic acid, and 1 pt. sulphuric acid, cohobating the product several times, agitating with water the oil which remains in the retort, and rectifying over massicot. It is a limpid liquid, of specific gravity 1·3, boiling at 262° C. (Herzog); at 266°, when the correction is made for the column of mercury projecting above the retort (H. Kopp). Vapour-density = 6·537 at 291° C. (by calculation for 2 vol. = 6·101).

Cinnamate of ethyl is nearly insoluble in water, but dissolves readily in alcohol and in ether. It is scarcely attacked by fuming nitric acid. Alkaline hydrates easily convert it into alcohol and a cinnamate of the alkali-metal.

Cinnamate of Methyl, $C^{10}H^{10}O^2 = C^9H^7(CH^3)O^2$. (E. Kopp, Compt. rend. xxi. 1376).—Obtained by saturating a mixture of cinnamic acid and wood-spirit with hydrochloric acid gas at a gentle heat, precipitating the product with water, then drying and rectifying. It is a colourless, oily liquid, having an agreeable aromatic odour. Specific gravity 1·106. Boiling point 241° C.

Cinnamate of Benzyl, or *Cinnamein* (p. 982).

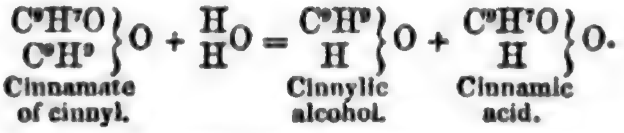
Cinnamate of Cinnyl, $C^{18}H^{16}O^2 = C^9H^7O(C^9H^9)O$. *Cinnamyl-styrone, Styracin.* (Bonastre, J. Pharm. June, 1831, p. 338.—E. Simon, Ann. Ch. Pharm. xxxi. 365.—E. Kopp, Compt. chim. 1850, p. 140.—Toel, Ann. Ch. Pharm. lxx. 1.—Strecker, *ibid.* lxx. 40; lxxiv. 112.—Plantamour, *ibid.* xxvii. 239; xxx. 341.—Gössmann, *ibid.* xcix. 376.—Scharling, *ibid.* xcvii. 90, 174.—Gm. xiii. 286.—Gerh. iii. 403.)—This compound, which bears to cinnylic alcohol or styrone (p. 992) the same relation that acetate of ethyl bears to common alcohol, is contained in liquid storax (p. 497), together with cinnamic acid, styrol, and several resins; also in balsam of Peru.

Preparation from Storax.—1. The balsam is distilled with water to expel the styrol, and then boiled with aqueous carbonate of sodium, which extracts the free cinnamic acid. The residue thus obtained is a resinous spongy mass, which contains oily styracin in its pores, and when kneaded with the fingers becomes more and more compact, while the oily styracin runs out.—2. Toel dries the resinous cake which remains after boiling the liquid storax with carbonate of sodium, after it has been freed from the solution of cinnamate of sodium; macerates it repeatedly with cold alcohol, which extracts the colouring resin, and leaves most of the styracin but little coloured; and obtains the styracin quite pure by repeated crystallisation from ether-alcohol.—3. Wolff allows the resinous cake to stand for some time in cold alcohol, when it soon becomes crystalline; frees the crystals from resin by dissolving them in boiling alcohol, and precipitating the resin with acetate of lead; and frequently recrystallises, first from ether-alcohol, then from ether.—4. After distilling liquid storax with water, and repeatedly boiling the residue with carbonate of sodium, the undissolved portion is slowly allowed to cool to 30°—40°: the mass then becomes tough and spongy, and a yellow oil collects in its pores. This oil made to run out by kneading and pressing, and then filtered, solidifies after some time into a crystalline mass, which is purified by recrystallisation from alcohol. The residual mass still contains much styracin, and is therefore worked up for styrone (E. Kopp).—5. The residue left after distilling liquid storax with water, separates when repeatedly boiled with carbonate of sodium, into a solid, dark resin, and liquid styracin. The latter is poured off, transferred to a flask, which is placed in an oil-bath at the temperature of 180° C., and distilled by passing steam heated to 180° through it; it then passes over as a white milky oil, which, when freed from water, solidifies on standing in open vessels, to a faintly coloured crystalline mass, which may be recrystallised from alcohol (Scharling).—8. Liquid storax is macerated or digested at a temperature not exceeding 30° C. with 5 to 6 pts. of dilute soda-ley, till the residue becomes colourless; this residue is collected, washed, dried and dissolved in alcohol containing ether; and from the solution, which, if not colourless, is to be rendered so by treatment with animal charcoal, pure styracin crystallises out. (Gössmann.)

Properties.—Cinnamate of cinnyl, or styracin, crystallises in tufts of beautiful prisms, destitute of taste and odour, insoluble in water, sparingly soluble in cold alcohol, very soluble in ether. It melts at 44° C. (Toel, Scharling), at 38° (E. Kopp), and remains liquid and viscous for a long time after cooling. It distils without decomposition in steam heated to 180° C. (Scharling.)

In treating storax as above described, styracin is sometimes obtained in a liquid, uncrystallisable state, especially if it has been left too long in contact with acids to free it from the last traces of soda.

Decompositions.—Styracin in contact with caustic alkalis solidifies to a mass of agglomerated granules. When distilled with potash, especially with strong alcoholic potash, it is decomposed like other compound ethers, yielding cinnylic alcohol (styrone) and cinnamate of potassium:



$$\underset{\substack{\text{Cinnamate}\\ \text{of cinnyl.}}}{\left.\begin{matrix}C^9H^7O\\ C^9H^9\end{matrix}\right\}O} + \begin{matrix}H\\ H\end{matrix}O = \underset{\substack{\text{Cinnylic}\\ \text{alcohol.}}}{\left.\begin{matrix}C^9H^9\\ H\end{matrix}\right\}O} + \underset{\substack{\text{Cinnamic}\\ \text{acid.}}}{\left.\begin{matrix}C^9H^7O\\ H\end{matrix}\right\}O}.$$

Heated with *nitric acid* it yields hydride of benzoyl, hydrocyanic acid, benzoic acid, and nitrobenzoic acid. With *chromic acid*, it yields hydride of benzoyl, benzoic acid, and a resin. With a mixture of *sulphuric acid and peroxide of manganese*, it yields hydride of benzoyl. With *strong sulphuric acid*, it yields cinnamic acid and a brown substance, soluble in water, insoluble in saline solutions.

Substitution-derivatives of Cinnamic Acid.

Bromocinnamic Acid. $C^9H^7BrO^2$.—This acid is obtained by passing bromine vapour in excess over cinnamate of silver, treating the decomposed salt with ether, and evaporating the filtered solution. A thick oil then remains, which dissolves partially in potash, and the alkaline solution decomposed by hydrochloric acid deposits crystals of bromocinnamic acid. The portion of the oil insoluble in potash is probably a bromide of carbon.

Bromocinnamic acid decomposes partially when dissolved in water and evaporated. It forms easily soluble salts with all bases, and does not precipitate nitrate of silver. (Herzog.)

Chlorocinnamic Acid. $C^9H^7ClO^2$. (E. Kopp. J. Pharm. [3] xvi. 426.—Toel, Ann. Ch. Pharm. lxx. 7.)—Obtained: 1. By passing chlorine into a cold solution of cinnamic acid in concentrated carbonate of sodium (Kopp).—2. By the action of alcoholic potash on an alcoholic solution of chlorostyracin, a chlorinated oil and chloride of potassium being formed at the same time. The mixture soon solidifies to a pulp, which is washed with alcohol, pressed, dissolved in a small quantity of boiling alcohol, and mixed with excess of hydrochloric acid. Chlorocinnamic acid then crystallises out on cooling, and may be purified by recrystallisation.

The acid crystallises in long shining odourless needles, melting at 132° C., and subliming at a higher temperature. Its vapour excites coughing. It is sparingly soluble in cold water, melts in boiling water, dissolves easily in alcohol and ether.

Chlorocinnamate of Ammonium, $2C^9H^6Cl(NH^4)O^2 + aq.$, forms curved arborescent needles. The *potassium-salt* forms lustrous pearly flakes. The *barium-salt*, $2C^9H^6ClBaO^2 + aq.$, is precipitated as a white powder, soluble in boiling water, and crystallising therefrom in shining laminæ. The *calcium-salt* is sparingly soluble, and resembles the barium-salt. The *silver-salt*, $C^9H^6ClAgO^2$, is obtained by precipitation from hot solutions, in slender needles which blacken on exposure to light.

Chlorocinnamate of Cinnyl or *Chlorostyracin*. $C^{18}H^{12}Cl^4O^2$.—Chlorine converts styracin into a viscid substance, having an acrid taste and an odour like that of copaiba balsam. It is insoluble in water, soluble in boiling alcohol and ether, whence it separates in the amorphous state. It is decomposed by potash, yielding a chlorinated oil, chlorocinnamate of potassium, and chloride of potassium. Distilled in a current of chlorine, it forms a volatile chlorinated liquid and a crystallisable chlorinated acid, the salts of which also crystallise readily. (E. Kopp.)

Nitrocinnamic Acid. $C^9H^7(NO^2)O^2$. (Mitscherlich, Ann. Ch. Phys. [3] iv. 73.—E. Kopp, Compt. chim. 1849, p. 146; Compt. rend. liii. 634.—J. Wolff, Ann. Ch. Pharm. lxxv. 303.)—This acid is produced by the action of strong nitric acid on cinnamic acid (**Mitscherlich, Kopp**), or by heating styrone with nitric acid, to which urea is added to prevent formation of nitrous acid (**Wolff**). To prepare it, concentrated nitric acid is freed from nitrous acid by boiling, and after cooling, about one-eighth of cinnamic acid is added. The cinnamic acid dissolves in a few minutes without disengagement of gas, the liquid becomes heated to 40° C., and a mass of crystals is deposited. In order to obtain larger quantities, cinnamic acid is triturated with nitric acid and cooled, so that the temperature may not rise above 50°; the mass is washed with cold water, till all nitric acid is removed, then dissolved in boiling alcohol and filtered; and the resulting crystals are washed with cold alcohol (**Mitscherlich**). Kopp dissolves 1 pt. of powdered cinnamic acid in 3 pts. of monohydrated nitric acid freed from nitrous acid by passing a dry stream of air through it, the mixture then solidifying almost immediately, in consequence of the crystallisation of the nitrocinnamic acid; washes the magma with water; then dries, and sets it aside for twenty-four hours with 4 pts. of cold alcohol, which removes any benzoic acid that may be present.

The acid forms very small white crystals, with a faint yellowish tint. It melts at about 270° C., and solidifies to a mass of crystals on cooling; boils a little above 270°, with decomposition. It is nearly insoluble in cold water, and dissolves but sparingly in boiling water; 1 pt. of it dissolves in 327 pts. of absolute alcohol at 20° C. Boiling hydrochloric acid dissolves it without decomposition (**Mitscherlich.**) With *sulphide of ammonium* it forms carbostyril. When it is dissolved in alcoholic sulphide of ammonium, sulphur separates on gently warming the liquid, while a yellow resin and an alkaloïd remain dissolved. Nitrocinnamic acid may be boiled with excess of alkali without decomposition.

Nitrocinnamic acid is but a feeble acid; nevertheless it forms neutral salts, and decomposes alkaline carbonates. The nitrocinnamates of the alkali-metals are very soluble, the rest are insoluble or sparingly soluble; they deflagrate when quickly heated, especially the potassium- and sodium-salts.

Nitrocinnamate of Ammonium gives off its ammonia when evaporated to dryness; its solution precipitates the salts of calcium, strontium, and magnesium when they are concentrated, but not when they are dilute.

Nitrocinnamate of Barium, $2C^9H^6(NO^2)BaO^2 + 3aq.$, crystallises from a boiling solution on cooling, in stellate groups of yellowish needles. The *strontium-salt*, $2C^9H^6(NO^2)SrO^2 + 5aq.$, may be obtained in small yellowish crystals grouped in nodules; it is moderately soluble in cold water. The *calcium-salt*, $2C^9H^6(NO^2)CaO^2 + 3aq.$, forms small yellowish white agglomerated grains having a crystalline aspect. The *magnesium-salt*, $C^9H^6(NO^2)MgO^2 + 3aq.$, crystallises in yellowish white nodules, which dissolve with tolerable facility in water, especially if warm.

Nitrocinnamate of Copper.—Bluish-white precipitate, which becomes darker when air-dried. When mixed with sand and distilled, it yields benzoic acid, nitrocinnamene having the odour of oil of cinnamon, and a small quantity of nitrobenzene.

Mercuric Nitrocinnamate, $C^9H^6(NO^2)HgO^2$, is thrown down from boiling solutions of mercuric chloride and an alkaline nitrocinnamate, as a brownish anhydrous precipitate. The mother-liquors deposit on cooling a crystalline mass of very light bulky arborescent tufts, consisting of the double salt, $2(HgCl.2C^9H^6(NO^2)HgO^2) + 3aq.$

Nitrocinnamate of Potassium. $C^9H^6(NO^2)KO^2$.—Very soluble; crystallises in mamellated groups by spontaneous evaporation. From solution in boiling alkaline ley, it crystallises in prismatic needles. The *sodium-salt* resembles the potassium-salt.

Nitrocinnamate of Silver. $C^9H^6(NO^2)AgO^2$.—Yellowish white insoluble precipitate, which, when cautiously heated, decomposes with projection of the silver.

NITROCINNAMIC ETHERS.—The *ethyl-compound*, $C^{11}H^{11}NO^4 = C^9H^6(NO^2)(C^2H^5)O^2$, is formed by heating nitrocinnamic acid with alcohol and sulphuric acid (**Mitscherlich**, J. pr. Chem. xxii. 194), or by the action of strong nitric acid on cinnamate of ethyl (E. **Kopp**, Compt. rend. xxiv. 615). It crystallises in prisms, which melt at 136° C.; boils with decomposition at 300°. Potash at the boiling heat converts it into alcohol and nitrocinnamate of potassium.

Nitrocinnamate of Methyl. $C^{10}H^9NO^4 = C^9H^6(NO^2)(CH^3)O^2$. (E. **Kopp**, Compt. rend. liii. 636.)—Obtained by heating nitrocinnamic acid with methylic alcohol, mixed with a small quantity of sulphuric acid or saturated with hydrochloric acid gas. The mixture thickens at first, then liquefies again, and finally a brown liquid is obtained, from which the ether separates as a crystalline mass, which may be purified by pressure and recrystallisation from alcohol. It forms white, delicate, rather elongated needles, sparingly soluble in cold alcohol and ether, and having but little odour; melts at 161° C. to a colourless liquid, which solidifies in a crystalline mass on cooling. At about 200° C. it begins to sublime in iridescent crystalline plates, and at 200° it boils. It dissolves in alcoholic sulphydrate of ammonium, forming a red liquid, which afterwards turns brown, and when heated yields an abundant crystallisation of sulphur.

CINNAMIC ALCOHOL. See Cinnylic Alcohol.

CINNAMIC ALDEHYDE. See Cinnamyl, Hydride of.

CINNAMIC ANHYDRIDE. $C^{18}H^{14}O^3 = (C^9H^7O)^2.O$. *Cinnamate of Cinnamyl. Cinnamic Cinnamate, Anhydrous Cinnamic Acid.* (Gerhardt, Ann. Ch. Phys. [3] xxxvii. 285.)—Produced by the action of oxychloride of phosphorus on well dried cinnamate of sodium, the best proportions being 1 pt. of the former to 6 pts. of the latter. The product is washed with water and carbonate of sodium, then dried and dissolved in boiling alcohol. It may also be obtained by the action of chloride of cinnamyl on neutral oxalate of potassium. It crystallises from the alcoholic solution as a white crystalline substance, composed of microscopic needles. It is insoluble in cold alcohol, and dissolves but slightly even in boiling water, becoming acid at the same time. It melts at 127° C.

Aceto-cinnamic Anhydride. $C^2H^3O.C^9H^7O.O$. See Acetic Anhydride (p. 21).

Benzo-cinnamic Anhydride. $C^7H^5O.C^9H^7O.O$. See Benzoic Anhydride (p. 558).

Nitrocinnamic Anhydride. $C^{18}H^{12}N^2O^7 = [C^9H^6(NO^2)O]^2.O$. (Chiozza, Ann. Ch. Phys. [2] xxxix. 231.—Gerh. iii. 388.)—Produced by the action of oxychloride of phosphorus on nitrocinnamate of potassium. It melts in boiling water more easily than nitrocinnamic acid, forming a yellow kneadable resin. It easily takes up water, and is converted into nitrocinnamic acid. With ammonia, it easily forms nitrocinnamide and nitrocinnamate of ammonium. With alcohol, it forms nitrocinnamate of ethyl. It is sparingly soluble in ether.

CINNAMIC ETHERS. See page 986.

CINNAMIDE. $C^9H^9NO = N.H^2.C^9H^7O$.—Chloride of cinnamyl treated with dry ammonia, yields sal-ammoniac, together with a white substance which dissolves in boiling alcohol, and separates in delicate needles in cooling. (Cahours.)

Nitrocinnamide. $C^9H^8N^2O^3 = N.H^2.C^9H^6(NO^2)O$. (Cahours, Ann. Ch. Phys. [3] xxvii. 452.)—Prepared: 1. By the action of aqueous ammonia on the product obtained by treating nitrocinnamate of potassium with oxychloride of phosphorus. After an hour's digestion at a gentle heat, the reaction is complete, and the nitrocinnamic anhydride is completely transformed into nitrocinnamide and nitrocinnamate of ammonium, which remains in solution. The nitrocinnamide is collected on a filter and purified by crystallisation from boiling water.—2. By the action of alcoholic ammonia on nitrocinnamate of ethyl; this process, however, takes a long time, and requires a large quantity of alcohol.

Nitrocinnamide separates from solution in boiling water in shortened, lustrous needles, sometimes in grains and laminæ having the appearance of flies' wings. It melts and turns brown between 155° and 160° C., and decomposes completely at 260°. It dissolves sparingly in cold alcohol, moderately in ether, and separates from solution in boiling alcohol in small, very regular, hemispherical concretions, smooth in the upper, and nodular in the lower part. It dissolves in caustic potash, producing a red solution, without evolution of ammonia.

Phenyl-Cinnamide. *Cinnanilide.* $N.H.C^6H^5.C^9H^7O$. (Cahours, Ann. Ch. Phys. [3] xxiii. 344.)—Produced by the action of phenylamine on chloride of cinnamyl. It dissolves easily in hot alcohol, and separates in slender needles on cooling. It melts at a gentle heat, and distils completely at a higher temperature. Potash-solution scarcely attacks it, even with aid of heat; but when fused with hydrate of potassium, it gives off phenylamine.

Nitranisyl-Cinnamide. *Cinnitranisidine.* $C^{16}H^{14}N^2O^4 = N.H.C^7H^6(NO^2)O.C^9H^7O$.—Produced by the action of chloride of cinnamyl on nitranisidine (p. 304). Yellowish needles, sparingly soluble in cold, more soluble in boiling alcohol. (Cahours.)

CINNANILIDE. Syn. with Phenyl-Cinnamide (*vid. sup.*)

CINNHYDRAMIDE. $C^{27}H^{24}N^2 = N^2(\overset{\prime\prime}{C^9H^8})^3$.—A compound produced by the action of ammonia on hydride of cinnamyl. It is analogous to hydrobenzamide, $C^{21}H^{18}N^2$, and is therefore more properly called hydrocinnamide (*q. v.*)

CINNAMON, OIL OF, and **OIL OF CASSIA.** These oils, which are nearly identical in composition, are obtained from the bark of different trees of the genus *Cinnamonum*, order *Lauraceæ*, viz. oil of cinnamon from Ceylon cinnamon, *Cinnamomum Zeylanicum;* and oil of cassia, from the bark of Chinese cinnamon, *Cinnamomum aromaticum*, or from *cassia buds*, the undeveloped flowers of *Cinnamomum Lauresii* (Nees). The oils are prepared by softening the bruised bark or flowers with salt water, distilling quickly, and drying with chloride of calcium. Oil of cinnamon has a more agreeable odour than oil of cassia, and is therefore more esteemed.

Both the oils consist mainly of cinnamic aldehyde, which may be separated by means of an acid sulphite of alkali-metal (p. 991); also a hydrocarbon, not yet examined, in variable, but always very small quantity, together with cinnamic acid, and resins.

Old samples often deposit crystals of cinnamic acid. The density of the oils varies from 1·025 to 1·05; their boiling point from 220° to 225° C.

Resins from Cinnamon-oil.—Old samples of the oil are more or less coloured and charged with resinous matters, which remain, after the oil has been distilled with salt water, the residue treated with cold water, to extract the salt, and afterwards with boiling water, to extract cinnamic acid. According to Mulder (Ann. Ch. Pharm. xxxiv. 149), there are two resins formed in the oil by atmospheric oxidation; one, α, soluble in cold alcohol, melting at 60° C., and containing 78·33 per cent. carbon, 6·49 hydrogen, and 15·18 oxygen; the other, β, sparingly soluble only in hot alcohol, melting at 145°, and containing 83·45 per cent. C, 6·06 H, and 10·49 O.

Mulder likewise describes several other resins, some soluble, others insoluble in alcohol, produced by treating oil of cinnamon with sulphuric acid, hydrochloric acid, and ammonia: they have all nearly the same composition as the β-resin, produced by atmospheric oxidation. (Gm. xiii. 264.)

CINNAMON-STONE. A variety of garnet (*q. v.*)

CINNAMYL. C^9H^7O.—The monatomic radicle of cinnamic acid and its derivatives. The following is a list of its compounds, and of those of the derived radicles, chlorocinnamyl, &c.

Type HH:

Chloride of Cinnamyl	$C^9H^7O.Cl$
Cyanide of Cinnamyl	$C^9H^7O.Cy$
Hydride of Cinnamyl: *Cinnamic Aldehyde*	$C^9H^7O.H$
Hydride of Tetrachlorocinnamyl: *Chlorocinnose*	$C^9H^3Cl^4O.H$

Type HHO:

Hydrate of Cinnamyl: *Cinnamic Acid*	$C^9H^7O.H.O$
Hydrate of Bromocinnamyl: *Bromocinnamic Acid*	$C^9H^6BrO.H.O$
Hydrate of Chlorocinnamyl: *Chlorocinnamic Acid*	$C^9H^6ClO.H.O$
Hydrate of Nitrocinnamyl: *Nitrocinnamic Acid*	$C^9H^6(NO^2)^2O.H.O$
Oxide of Cinnamyl: *Cinnamic Anhydride*	$(C^9H^7O)^2O$
Oxide of Cinnamyl and Acetyl: *Aceto-cinnamic Anhydride*	$C^9H^7O.C^2H^3O.O$
Oxide of Cinnamyl and Benzol: *Benzo-cinnamic Anhydride*	$C^9H^7O.C^7H^5O.O$
Oxide of Nitrocinnamyl: *Nitrocinnamic Anhydride*	$[C^9H^6(NO^2)O]^2O$

Type NH^3:

Cinnamide	$N.H^2.C^9H^7O$
Phenyl-cinnamide: *Cinnanilide*	$N.H.C^6H^5.C^9H^7O$
Nitranisyl-cinnamide: *Cinnitranisidine*	$N.H.C^7H^6(NO^2)O.C^9H^7O$

The compounds of cinnamyl are intimately related to those of benzoyl, C^7H^5O, and are easily converted by oxidising reagents into hydride of benzoyl and benzoic acid. Cinnamic acid heated with excess of hydrate of potassium, is resolved, with evolution of hydrogen, into acetic and benzoic acids (p. 984).

CINNAMYL, CHLORIDE OF. $C^9H^7O.Cl$. (Cahours, Ann. Ch. Phys. [3] xxiii. 341.—Béchamp, Compt. rend. xlii. 224.)—This compound is produced by the action of trichloride or pentachloride of phosphorus on cinnamic acid. When the pentachloride is used, the product is distilled, the portions which pass over between 250° and 265° C. being collected apart and rectified (Cahours). With the trichloride, the mixture must be heated to between 60° and 120° C., as long as hydrochloric acid continues to escape. It then melts and forms two layers, the upper of which, consisting of chloride of cinnamyl, is decanted and distilled. (Béchamp.)

Chloride of cinnamyl is a heavy oil, of specific gravity 1·207, boiling at 262° C. In a moist atmosphere it decomposes quickly, yielding hydrochloric acid and fine crystals of cinnamic acid. In contact with alcohol, it becomes strongly heated, and if water be then poured upon the mixture, cinnamate of ethyl separates as a heavy oil. With ammonia and phenylamine, it yields cinnamide and phenyl cinnamide respectively. Heated with cinnamate of sodium, it yields cinnamic anhydride.

CINNAMYL, CYANIDE OF. $C^{10}H^7NO = C^9H^7O.Cy$. (Cahours, *loc. cit.*)—Produced by distilling chloride of cinnamyl with cyanide of potassium or cyanide of mercury. A liquid then passes over, which rapidly turns brown when exposed to the air, yielding hydrocyanic and cinnamic acids. It still contains chlorine, but consists for the most part of cyanide of cinnamyl.

CINNAMYL, HYDRIDE OF. $C^9H^8O = C^9H^7O.H$. *Cinnamic Aldehyde.* (Dumas and Péligot, Ann. Ch. Phys. lvii. 305.—Mulder, Ann. Ch. Pharm. xxxiv.

147.—**Bertagnini**, *ibid.* lxxxv. 272.—**Gm.** xiii. 258.—**Gerh.** iii. 373.)—This compound forms the essential part of oil of cinnamon or oil of cassia, and may be separated therefrom by the action either of nitric acid or of the acid sulphites of the alkali-metals.

a. When commercial oil of cinnamon is shaken up with strong nitric acid, large crystals are formed, after two or three hours, consisting of a compound of nitric acid with cinnamic aldehyde, which, when collected on a filter, so as to allow the still liquid portion to drain off, and then decomposed by water, yields pure cinnamic aldehyde. (**Dumas** and **Péligot.**)

b. Oil of cinnamon is agitated with three or four times its volume of a solution of acid sulphite of potassium of 28°—30° Bm; and the crystalline mass, which forms in a few minutes, is separated from the mother-liquor, left to dry on a filter, then pulverised, washed with cold alcohol, again dried, and dissolved at a gentle heat in dilute sulphuric acid. A large quantity of sulphurous acid is then given off, and the cinnamic aldehyde rises to the surface as an oil, which may be purified by washing and drying.

Cinnamic aldehyde is a colourless oil rather heavier than water. It may be distilled without decomposition, either in vacuo, or with water which has been freed from air by boiling. When exposed to the *air*, it quickly becomes yellow and resinous, and acquires an acid reaction. It rapidly absorbs *oxygen* gas, especially if moist, and is thereby converted into cinnamic acid. Heated with *nitric acid*, it forms benzoic acid and hydride of benzoyl. *Chromic* acid converts it into benzoic and acetic acids (**Persoz**). Boiled with solution of *hypochlorite of calcium*, it yields benzoate of calcium. Strong *sulphuric acid* converts it into a resinous mass.

Cinnamic aldehyde gradually heated in a stream of *chlorine*, forms at first a liquid compound, which solidifies when treated with a strong solution of potash. When distilled four or five times in a stream of chlorine, it is converted into tetrachlorocinnamyl. With *pentachloride of phosphorus*, it yields hydrochloric acid and chloride of cinnamyl. Fused with *hydrate of potassium*, it forms cinnamate of potassium, with evolution of hydrogen:

$$C^9H^8O + KHO = C^9H^7KO^2 + H^2.$$

Ammonia-gas converts it into cinnhydramide:

$$3C^9H^8O + 2NH^3 = C^{27}H^{24}N^2 + 3H^2O.$$

Compounds of Cinnamic Aldehyde.

a. *With Hydrochloric Acid.*—Oil of cinnamon absorbs a large quantity of hydrochloric acid gas, acquiring a green colour and becoming thicker. 100 pts. of the oil take up 26·9 pts. of hydrochloric acid.

b. *With Iodine and Iodide of Potassium.*—When cinnamon-water is placed in contact with iodine and iodide of potassium and cooled to 0° C., a crystallisable compound, $C^9H^8O.I^8.KI$, is formed. It crystallises from alcohol and ether, but water decomposes it, setting free the cinnamic aldehyde. An excess of iodide of potassium prevents the decomposition. (**Apjohn**, Ann. Ch. Pharm. xxviii. 314.)

c. *With Nitric Acid.* $C^9H^8O.HNO^3$.—Produced when strong nitric acid is left in contact with cinnamic aldehyde. It forms oblique, rhomboïdal prisms, often two or three inches long. After being drained, they may be preserved for some hours, but the least rise of temperature or atmospheric humidity quickly decomposes them. When treated with water, they yield pure cinnamic aldehyde.

Nitrate of cinnamic aldehyde kept in an imperfectly closed vessel, yields after a few days a red liquid, which has the characteristic odour of bitter-almond oil, is converted by ammonia-gas into nitrate of ammonium and a red resin; and is dissolved by strong sulphuric acid, the solution yielding with water a precipitate of cinnamic acid.

d. *With Acid Sulphites of Alkali-metals.*—Cinnamic aldehyde dissolves easily in aqueous acid sulphite of ammonium, forming an oily liquid, which afterwards solidifies to a crystalline pulp. Oil of cassia shaken up with a strong solution of acid sulphite of ammonium soon solidifies to a yellow crystalline mass, which may be purified from the hydrocarbon and other substances which the oil contains, in addition to cinnamic aldehyde, by washing with alcohol of 80 or 90 per cent. (**Gössmann**). The compound is very unstable, quickly turning brown, even when kept in closed vessels.

The *potassium-salt* is obtained by agitating oil of Ceylon or Chinese cinnamon with three or four times its volume of a solution of acid sulphite of potassium of 28° to 30° Bm.; after washing with alcohol and recrystallisation from boiling alcohol, it forms beautiful silvery plates nearly inodorous and permanent in the air. It is soluble in cold water, but the solution is decomposed by heat, giving off sulphurous acid and yielding colourless drops of cinnamic aldehyde. Heated in a test-tube, it gives off water, sulphurous acid, and cinnamic aldehyde, which, by contact with the air, is converted into cinnamic acid. Bromine and iodine dissolve in the aqueous solution without colouring it, but converting the sulphurous acid into sulphuric acid, and setting free the cinnamic aldehyde. Bromine in excess produces a solid, slightly aromatic substance fusible in hot water.

Sodium-salt.—Oil of cinnamon mixed with solution of acid sulphite of sodium of 37° Bm. forms a crystalline fibrous substance, which, if left to itself, soon becomes completely liquid; at the same time there is formed an oil which is not solidified, either by acid sulphites of alkali-metal or by nitric acid, the sulphite of cinnamyl-sodium apparently remaining dissolved. The liquid, if left to evaporate, yields crystals of sulphate of sodium, together with opaque crystalline nodules, which dissolve in boiling alcohol, forming a solution which on cooling deposits long thin needles arranged in spiral groups. (Bertagnini.)

Hydride of Tetrachlorocinnamyl. *Chlorocinnose.* $C^9H^3Cl^4O.H$. (Dumas and Péligot, Ann. Ch. Phys lvii. 316.)—By repeatedly distilling hydrate of cinnamyl in chlorine gas, this compound is obtained in long white very volatile needles. It melts at a gentle heat and sublimes without decomposition. It is soluble in alcohol. It is not decomposed by strong sulphuric acid, even at the boiling heat, and may be volatilised without alteration in a current of dry ammonia.

The formation of this substance is preceded by that of several liquid compounds, one of which, perhaps *hydride of monochlorocinnamyl*, solidifies in contact with potash-ley.

CINNYL. C^9H^9.—The radicle of the compound usually called *cinnamic* alcohol or *styrone.* Cinnyl bears to cinnamyl, C^9H^7O, the radicle of cinnamic acid, the same relation that ethyl, C^2H^5, bears to acetyl, C^2H^3O.

CINNYLIC ALCOHOL. $C^9H^{10}O = C^9H^9.H.O$. *Hydrate of Cinnyl, Cinnamic Alcohol, Styrone, Styracone, Styrax-Alcohol, Styrylic Alcohol, Peruvin.* (E. Simon, Ann. Ch. Pharm. xxxi. 274.—Toel, *ibid.* lxx. 3.—Strecker, *ibid.* lxx. 10.—J. Wolff, *ibid.* lxxxv. 299.—E. Kopp, Compt. chim. 1850, p. 113.—Scharling, Ann. Ch. Pharm. cxv. 90, 183.—Gm. xiii. 256.—Gerh. iii. 402.)—This compound is obtained by cautiously distilling styracin with a strong solution of caustic potash or soda. A milky liquid then passes over, from which, when saturated with common salt, a creamy substance separates, gradually collecting on the surface in an oily layer and solidifying (Toel). Wolff dissolves styracin in boiling alcoholic potash; mixes water with the liquid; filters from cinnamate of potassium; and separates the precipitated cinnamic alcohol from undecomposed styracin by distillation.

Cinnylic alcohol forms beautiful soft silky needles, having a sweet taste and an agreeable odour of hyacinths. It melts at 33° C., and volatilises without alteration at a higher temperature. It is moderately soluble in water, very soluble in alcohol, in ether, in styrol, and in oils, both fixed and volatile. When the aqueous solution saturated at the boiling heat is left to cool, it becomes milky, and does not clarify for several hours, when it becomes filled with needle-shaped crystals.

CIPOLINO. A white marble with shadings or zones of green talc, found in Italy.

CISSAMPELINE. Syn. with Pelosine (*q. v.*)

CITRACONAMIDES and **CITRACONANILIDES.** See Amides of Citraconic Acid (p. 993).

CITRACONIC ACID. *Pyrocitric Acid.* $C^5H^6O^4$. (Lassaigne [1822], Ann. Ch. Phys. xxi. 100.—Dumas, *ibid.* cxi. 21.—Robiquet, *ibid.* lxv. 78.—Liebig, Ann. Ch. Pharm. xxvi. 119, 152.—Crasso, *ibid.* xxxiv. 68.—Engelhardt, *ibid.* lxx. 246.—Gottlieb, *ibid.* lxxvii. 265.—Baup, Ann. Ch. Phys. [3] xxxiii. 192.—Gm. x. 417.—Gerh. ii. 120.)—This acid, or rather its anhydride, is produced by the dry distillation of citric acid, constituting in fact the chief portion of the distillate (p. 995). The anhydride rapidly attracts moisture, and when exposed to the air, is converted into a crystalline mass of citraconic acid, which is freed from excess of water by pressure between blotting-paper and exposure to a temperature of 50° C. Citraconic acid is also one of the products of the dry distillation of lactic acid.

Citraconic acid is inodorous, and has a sour and slightly bitter taste. It crystallises in four-sided prisms, dissolves in 8 pts. of water at 10° C., and is readily soluble in alcohol and in ether. It melts at 80° C.; small quantities of it kept for some time at 100° are converted into itaconic acid. By dry distillation it is resolved into citraconic anhydride and water.

When citraconic acid is heated with strong *nitric acid*, a violent reaction is set up, accompanied by disengagement of gas, and an oily body is produced, which on cooling solidifies to a crystalline mass, consisting of two crystalline nitro-compounds, eulyte and dyslyte, which dissolve in alcohol to an unequal extent; their composition is not known. By *dilute nitric acid*, citraconic acid is converted into *mesaconic acid.*

When *bromine* is gradually added to a strong solution of citraconate of potassium, carbonic acid is disengaged and a heavy yellowish oil separates, consisting of an acid and a neutral substance. The former is removed by treatment with dilute potash, which leaves the latter unaltered. When a weak acid is added to the alkaline solution, there is separated, sometimes a heavy oil and sometimes fine needles. These two bodies are identical in composition, and consist of an acid, $C^4H^6Br^2O^2$, which has been named by Cahours, its discoverer, *bromotriconic acid.* It has the composition of dibrominated butyric acid (p. 693); but Cahours did not obtain it by the action of bromine on butyric acid or butyrate of potassium. The liquid acid is slightly amber-coloured, and has a peculiar odour. When distilled, it gives off hydrobromic acid and leaves a carbonaceous residue. The liquid acid, after standing for some time, occasionally solidifies to a mass of crystals. When it is heated with concentrated potash, a peculiar odour is disengaged, and the addition of an acid no longer precipitates an oil. The acid forms a curdy precipitate with silver-solution, and its ammonium-salt crystallises.

The neutral oil formed in the preparation of the acid has the composition $C^3H^3Br^3O$, and may either be *tribromopropionic aldehyde* or *tribrominated acetone.*

By the action of *bromine* on citraconate of potassium, in presence of excess of hydrate of potassium, an oil is also separated and carbonic acid disengaged. When a weak solution of potash is added, the greater part dissolves, and a small quantity of tribromopropionic aldehyde remains; on adding dilute nitric acid to the alkaline solution, large white crystalline flakes are deposited, consisting of an acid which crystallises from alcohol and ether in long prisms. It has the composition of dibromopropionic acid, $C^3H^4Br^2O^2$, but Cahours names it bromitonic acid.

CITRACONATES.—Citraconic acid is a dibasic acid, and forms two series of salts, the *neutral salts*, $C^5H^4M^2O^4$, and the *acid salts*, $C^5H^5MO^4$; they are isomeric with the itaconates, mesaconates, and lipates. The acid salts mostly crystallise well.

The *acid barium-salt*, $C^5H^5BaO^4$, crystallises in large groups of fine silky needles.

The *neutral silver-salt*, $C^5H^4Ag^2O^4$, crystallises both anhydrous and with an atom of water. In an aqueous solution of citraconic acid, nitrate of silver produces, on addition of ammonia, a very bulky precipitate which dissolves in boiling water. On cooling, the salt is deposited in long needles. If the mother-liquor from this be slowly evaporated, hexagonal crystals are formed which have an adamantine lustre, and consist of the hydrated salt, $C^5H^4Ag^2O^4 + H^2O$.

The *acid silver-salt*, $C^5H^5AgO^4$, is obtained by dissolving the neutral salt in an acid solution of citraconic acid. On evaporation, large groups of crystals are obtained.

Citraconate of Ethyl, or *Citraconic Ether*, $C^9H^{14}O^4$, is obtained by repeatedly cohobating a mixture of alcohol, citraconic acid, and hydrochloric acid, and washing the distillate with water.

It is a colourless, bitter, somewhat aromatic liquid, of density 1·040 at 18°·5 C. It boils at 225° C. with partial decomposition. It is insoluble in water, but readily soluble in alcohol and in ether. In contact with water, it gradually acidifies and alcohol is formed. By potash it is decomposed into citraconate of potassium and alcohol. E. A.

CITRACONIC ACID, AMIDES OF:

CITRACONAMIDE, $C^5H^8N^2O^2 = N^2.H^4.(C^5H^4O^2)''$, is obtained as a yellow viscid mass, which becomes brittle and vitreous on cooling, when citraconic anhydride is heated in a stream of dry ammoniacal gas. It dissolves in water, and the solution on cooling yields citraconate of ammonium. It is derived from neutral citraconate of ammonium by the loss of 2 at. of water:

$$C^5H^4(NH^4)^2O^4 - 2H^2O = C^5H^8N^2O^2.$$

CITRACONIMIDE. $C^5H^5NO^2 = N.H.(C^5H^4O^2)''$.—Citraconic acid is mixed with excess of ammonia and evaporated to dryness, and the residue heated to 180° C. An amorphous oily yellow mass is left, which is citraconimide. It does not dissolve in cold water, and but slightly so in alcohol; it is highly hygroscopic. It is derived from acid citraconate of ammonium by the loss of 2 at. of water:

$$C^5H^5(NH^4)O^4 - 2H^2O = C^5H^5NO^2.$$

Phenylcitraconimide or *Citraconanil.* $C^{11}H^9NO^2 = N.C^6H^5.(C^5H^4O^2)''$.—When anhydrous citraconic acid is mixed with phenylamine, a brisk action ensues, and the mixture, if kept for some time in the water-bath, is totally converted into the above compound. It crystallises in colourless needles, which melt at 96° C., and sublime at a little above 100°. It is readily soluble in alcohol and in ether.

It is derived from acid citraconate of phenylamine by the loss of 2 at. of water:

$$C^5H^5(C^6H^8N)O^4 - 2H^2O = C^{11}H^9NO^2.$$

Iodophenylcitraconimide, $C^{11}H^8INO^2$, is obtained by substituting iodophenylamine in the above reaction.

Dinitrophenylcitraconimide, $C^{11}H^7(NO^2)^2NO^2$, is obtained by the action of a mixture of nitric and sulphuric acid on phenylcitraconimide.

Citraconamic Acid. $C^5H^7NO^3 = N.\overbrace{H^2.C^5H^4}^{'''}\overbrace{O^2.H}^{''}.O$.—Citraconimide appears to be partially convertible into this acid by boiling with ammonia. Its salts are uncrystallisable.

Phenylcitraconamic Acid, $C^{11}H^{11}NO^3 = N.H.\overbrace{C^6H^5.C^5H^4}^{'''}\overbrace{O^2.H}^{''}.O$, is obtained as an ammonium-salt by boiling phenylcitraconimide with dilute ammonia. On the addition of acetic acid, it is separated as a crystalline precipitate, which is washed with cold water. It is an unstable body. It is derived from acid citraconate of phenylamine by the loss of an atom of water:

$$C^5H^5(C^6H^8N)O^4 - H^2O = C^{11}H^{11}NO^3.$$

Dinitrophenylcitraconamic acid, $C^{11}H^9(NO^2)^2NO^3$, is obtained in a similar manner.
E. A.

CITRACONIC ANHYDRIDE. $C^5H^4O^3$.—This compound is produced by the dry distillation of citric acid, constituting the greater part of the crude product. On rectifying this crude distillate, two layers are formed, the upper being aqueous, and the lower an oily acid liquid which does not solidify.. This, which is citraconic anhydride, is purified by redistillation. The same substance is formed by heating itaconic acid.

Citraconic anhydride is a colourless inodorous liquid of specific gravity 1·247. It rapidly absorbs ammonia, with disengagement of heat, forming a vitreous deliquescent mass, which probably consists of citraconamic acid. E. A.

CITRACONIC CHLORIDE. *Pyrocitric Chloride, Chloride of Pyrocitryl.* $C^5H^4O^2Cl^2$.—When pentachloride of phosphorus is mixed with citraconic anhydride, a brisk action ensues, and on subsequent distillation, oxychloride of phosphorus passes over, followed by chloride of pyrocitryl when the temperature has reached 175° C. It contains, however, some citraconic anhydride, which raises the boiling point: it is freed therefrom by redistillation with pentachloride of phosphorus, the part distilling between 175°—190° being ultimately collected. It is a highly refracting fuming liquid, with a density of 1·4. With water, it forms citraconic and hydrobromic acids, and with absolute alochol, citraconic ether and hydrochloric acid. E. A.

CITRACONIC ETHER. See CITRACONATES (p. 993).

CITRAMIDES. See page 1000.

CITRACONIMIDE (p. 993).

CITRACONIODANIL. Syn. with IODOPHENYLCITRACONIMIDE (p. 993).

CITRENE. *Citronyl.* $C^{10}H^{16}$.—A liquid isomeric with oil of lemon, &c., obtained by distilling the solid di-hydrochlorate of lemon-oil over hydrate of potassium or quick lime. It is transparent and colourless, of specific gravity 0·8569, vapour-density 4·73 (by calculation for 2 vol. 4·71); boils at 165° C. It resembles oil of lemon in most of its properties, and in forming a crystallisable compound with hydrochloric acid, but differs from it in being without action on polarised light. (Gm. xiv. 303.)

CITRIC ACID. $C^6H^8O^7 = C^6H^5O^4.H^3.O^3$. (Scheele [1784], *Opuscula* ii. 181. —Berzelius, Ann. Chim. xciv. 171; Ann. Ch. Phys. lii. 424, 432; lxvii. 303; lxx. 215.—Robiquet, *ibid.* lxv. 68.—Liebig, Ann. Ch. Pharm. v. 134; xxvi. 119, 152; xliv. 57.—Marchand, J. p. Chem. xxiii. 60.—Cahours, Ann. Ch. Phys. [3] xix. 488.—Pebal, Ann. Ch. Pharm. lxxxii. 78; xcviii. 67.—Gm. xi. 436.—Gerh. ii. 85.) —The existence of a peculiar organic acid in the juice of lemons and of oranges has long been known, but the discovery of the separate identity of this acid, and its discrimination from tartaric acid, was first effected by Scheele in 1784, who gave to it the name it bears.

It is to the presence of citric acid that a great many fruits owe their acidity. This acid occurs in the free state in oranges, lemons, citrons, tamarinds, cherries, currants, gooseberries, raspberries, strawberries, whortleberries, and a great many others. In some of them it is associated with malic and tartaric acids. It is also contained in several tubers and bulbs, such as the potato and the onion. Occasionally it occurs as acid potassium or calcium salt.

Preparation.—The raw material for the production of citric acid is lemon juice. The juice is made to undergo an incipient fermentation; it is then filtered and neutralised, first with chalk and afterwards with quick lime, by which an insoluble citrate of calcium is formed: 10 pts. of this salt are carefully decomposed by a cold mixture of 9 pts. sulphuric acid and 56 of water; the gypsum is washed with cold water; and the filtrate and wash-water are boiled down in a leaden vessel over the naked fire until the liquor has the specific gravity 1·13, then concentrated over a water-bath until a saline film begins to form, when the liquid is immediately cooled to the crystallising point; if it were further concentrated, the excess of sulphuric acid would convert the residue into a black mass. The crystals formed are purified by four or five recrystallisations, and the mother-liquors are utilised for the preparation of citric acid by treatment with chalk, in the same manner as the fresh lemon juice. In the south of France, the citrate of calcium is bleached with chloride of lime, prior to its decomposition with sulphuric acid. Good lemons yield about 5½ per cent. of the crystallised acid.

The raw material generally used in this country for the preparation of citric acid on the large scale, for the use of calico-printers, is a black fluid, like thin treacle, which comes from Sicily, and is obtained by inspissating the expressed juice of the lemon after the rind has been removed for the sake of the essential oil. (*Ure's Dictionary of Arts, Manufactures and Mines*, i. 690.)

Citric acid may also be prepared from gooseberries. Tilloy (J. Pharm. xiii. 305) expresses the juice of the unripe berries; leaves it to ferment; distils off the alcohol formed; filters the residual liquid; and treats it with chalk in the same manner as in the preparation of the acid from lemon juice. 100 pounds of gooseberries give 10 pounds of spirit of specific gravity 0·928, and 1 pound of crystallised citric acid.

Properties.—Citric acid crystallises in two forms. A concentrated solution deposits by spontaneous evaporation, large, transparent, colourless prisms, having the composition $C^6H^8O^7 + H^2O$; this is the ordinary commercial acid. The crystals belong to the trimetric system, and generally have the faces $\infty P \,.\, \bar{P}\infty \,.\, \breve{P}\infty$ predominant, also with $\infty \bar{P} \infty$; the face $2\breve{P}\infty$ likewise occurs together with $\bar{P}\infty$, and sometimes without it. P also not unfrequently occurs subordinate. Ratio of brachydiagonal, macrodiagonal, and principal axis = 0·6068 : 1 : 0·4106. (*Kopp's Krystallographie*, p. 264; see also Gerh. ii. 88.) The crystals effloresce in the air between 28° and 50° C., and lose their water of crystallisation at 100°. A boiling concentrated solution of citric acid allowed to cool, deposits crystals of a different form, which, according to some chemists, contain $2C^6H^8O^7 + H^2O$; according to others, this water is only mechanically mixed.

Citric acid has a strong, but pleasant, acidity, in which respect it differs from tartaric acid, the acidity of which is accompanied by a somewhat bitter taste. This difference is still greater in the salts.

Citric acid is soluble in 0·75 pts. of cold and in 0·5 pts. of boiling *water*. It is readily soluble in *alcohol*, but insoluble in *ether*.

Citric acid and its potassium-salt are used in medicine. It is also used in the preparation of effervescent summer beverages. Its most extensive application is in dyeing and calico-printing; for certain of the finer colours, it cannot be replaced by less costly acids.

When *lime-water* is added to a solution of citric acid, a slight precipitate is formed, if the solution is concentrated and the lime-water present in great excess. But if the mixture be boiled, a considerable precipitate of citrate of calcium is formed, which redissolves as the solution cools. By this deportment, free citric acid is easily detected. It is distinguished from tartaric and racemic acids by the fact that its potassium-salt is soluble.

Decompositions.—1. Solution of citric acid, when kept for some time, becomes covered with fungi.—2. An aqueous solution mixed with chalk and exposed for some time to a temperature of 20°—30° C. in contact with a little *yeast*, yields acetic and butyric acids. According to How, when exposed in contact with *putrefying curd* and a base, it ferments and becomes converted into acetic and propionic acids.—3. When citric acid is heated in a retort, it first melts in its water of crystallisation and then boils, giving off the water, which condenses in the receiver. Afterwards at about 175° C. vapours of acetone distil over, and a copious disengagement of carbonic oxide takes place. At this time, the residue in the retort consists of aconitic acid. If the distillation be continued, carbonic acid is given off and oily striæ begin to appear in the neck of the retort, which solidify to crystals of itaconic acid. If these last crystals be repeatedly distilled, an oily mass of anhydrous citraconic acid is obtained, which no longer solidifies. These decompositions of citric acid are thus expressed:

$$\underset{\text{Dry citric acid.}}{C^6H^8O^7} \quad - \quad H^2O \quad = \quad \underset{\text{Aconitic acid.}}{C^6H^6O^6}.$$

$$\underset{\text{Aconitic acid.}}{C^6H^6O^6} \quad - \quad CO^2 \quad = \quad \underset{\text{Crystallised itaconic acid.}}{C^5H^6O^4}.$$

$$\underset{\text{Crystallised itaconic acid.}}{C^5H^6O^4} \quad - \quad H^2O \quad = \quad \underset{\text{Citraconic anhydride.}}{C^5H^4O^3}.$$

The acetone and carbonic oxide observed in an earlier stage of the decomposition are probably due to a secondary decomposition of aconitic acid, thus:

$$\underset{\text{Aconitic acid.}}{C^6H^6O^6} = 2CO^2 + CO + \underset{\text{Acetone.}}{C^3H^6O}.$$

Heated with *pumice*, citric acid gives off carbonic anhydride at 153° C.—4. Fused with *potash*, citric acid is decomposed into oxalic and acetic acids:

$$\underset{\text{Citric acid.}}{C^6H^8O^7} + H^2O = \underset{\text{Oxalic acid.}}{C^2H^2O^4} + \underset{\text{Acetic. acid.}}{2C^2H^4O^2}.$$

5. When citric acid is treated with strong *sulphuric acid*, a disengagement of carbonic oxide ensues, even without the application of heat. But if the temperature be raised the odour of acetone is perceived, and carbonic anhydride is given off. On adding carbonate of sodium to the residual liquid diluted with water, a brown resinous mass is precipitated, and the solution contains the sodium-salt of a peculiar acid, which does not precipitate baryta or strontia. — 6. Citric acid is not attacked by dilute *nitric acid;* but if heated for some time with strong nitric acid, it yields oxalic and carbonic acids.

7. Citric acid is easily oxidised by *permanganic acid.* A solution of citric acid mixed with sulphuric acid does not decolorise *permanganate of potassium* in the cold; but at 80° C. the citric acid is oxidised to carbonic acid and acetone:

$$2C^6H^8O^7 + H^2O + O^{10} = C^3H^6O + 9CO^2 + 6H^2O.$$

If a large excess of the permanganate be used, other products are likewise formed, namely, a body which strongly irritates the eyes and respiratory organs, reduces permanganate of potassium at common temperatures, and is turned brown by alkalis, probably therefore acrolein, together with an acid closely analogous to acrylic acid. Finely divided peroxide of manganese acts in the same way as the permanganate. (Péan de Saint Gilles, Ann. Ch. Phys. [3] lv. 374.)

8. *Chlorine* acts but feebly on citric acid. When a layer of concentrated solution of citric acid is exposed to the sunlight in a large globe filled with chlorine, the gas is slowly absorbed, and an oil gradually separates, which after rectification is colourless, has a sweetish burning taste, and a peculiar odour. It boils at 200°—201° C., and does not solidify at 0°. It reddens litmus paper only after prolonged contact. Plantamour, the discoverer of this body, assigns to it the formula $C^8Cl^{10}O^3$; when it is agitated with water and cooled to + 6°, a mass of crystals is formed, $C^8Cl^{10}O^3.3H^2O$, which melt and give off their water at 15°. The oil is attacked by potash, with formation of a body, $C^4Cl^4K^2O^4$. Städeler considers the oil to be hexachlorinated acetone C^3Cl^6O (p. 30), and the crystals to be a hydrate, $C^3Cl^6O + H^2O$. Laurent ascribes to the oil the formula $C^5Cl^{10}O^2$.

9. The action of chlorine on citrate of sodium, though not very energetic even in sunshine, is different. Carbonic acid is disengaged, and the liquor becomes milky from formation of an oil; at the same time, an acid citrate of sodium is formed, which crystallises in stellate groups. The odour of the oil, at first sweetish, becomes gradually more acrid. It is a mixture of several bodies. On rectification, chloroform first distils over at 64°—66° C.; the boiling point then rises to 188°—190°, and remains constant for some time; it then rises to 200°, at which point the oil produced by the free acid distils over. The intermediate product, on rectification, boils at 190°. It is a colourless and very fluid oil, of specific gravity 1·66, with a burning taste, an extremely irritating odour, and exciting tears. It has the formula $C^6Cl^{10}O^3$. The action of alcoholic potash on this oil yields chloride of potassium, and a very soluble potassium-salt which crystallises in satiny scales; it has the formula $C^4Cl^4K^2O^4$. The same salt is produced by the action of potash on the oil from the free acid. A corresponding silver-salt is very unstable, and is readily reduced to the metallic state even in the cold. The potassium-salt has the composition of that of a chlorinated succinic acid. The mother-liquor from which the chlorinated oil has been deposited contains, besides chloride of sodium, the sodium-salt of an acid which has the composition of succinic acid but appears to be only isomeric with it.

10. When *bromine* is gradually added to solution of citrate of potassium, a brisk disengagement of carbonic acid takes place; and if the addition of bromine be continued as long as gas is given off, and the excess of bromine carefully removed by potash, an oil is precipitated which is a mixture of two bodies. The most volatile of these is bromoform, $CHBr^3$. The other has received from Cahours the name bromoxaform. It consists of lustrous silky needles, which by spontaneous evaporation crystallise in large colourless plates. They melt between 74° and 75° C., but are gradually decomposed by distillation. The formula of the body is $C^3HBr^5O^2$ (pentachlorinated pro-

pionic acid): it is decomposed by potash, with formation of bromide of potassium, oxalic acid, and bromoform:

$$\underset{\text{Bromoxaform.}}{C^3HBr^5O^2} + 2KHO = 2KBr + \underset{\text{Oxalic acid.}}{C^2H^2O^4} + \underset{\text{Bromoform.}}{CHBr^3}.$$

11. Dried citric acid in contact with *pentachloride of phosphorus*, becomes heated, and yields oxychlorocitric acid and oxychloride of phosphorus:

$$C^6H^8O^7 + PCl^5 = C^6H^8O^6Cl^2 + POCl^3.$$

If the mixture be heated, hydrochloric acid is evolved, and chloride of citryl appears to be formed:

$$C^6H^8O^6Cl^2 + PCl^5 = \underset{\text{Chloride of citryl.}}{C^6H^5O^4Cl^3} + POCl^3 + HCl + H^2O.$$

If the heat be continued, the liquid assumes a deep cherry-red colour and then appears to contain chloride of aconityl:

$$C^6H^5O^4Cl^3 + PCl^5 = \underset{\text{Chloride of aconityl.}}{C^6H^3O^3Cl^3} + POCl^3 + 2HCl.$$

Citrates. Citric acid is a strong acid. It reddens blue litmus paper and expels carbonic acid from carbonates. An aqueous solution dissolves zinc and iron, with disengagement of hydrogen.

Citric acid is tribasic. It may be derived from 3 at. water in which 3 at. hydrogen are replaced by the triatomic radical citryl, $C^6H^5O^4$. It therefore forms three series of salts, in which 1, 2, or 3 at. hydrogen are replaced by metal, thus:—

Citric acid	$\left.\begin{matrix}(C^6H^5O^4)''' \\ H^3\end{matrix}\right\}O^3$
Acid monometallic citrate	$\left.\begin{matrix}(C^6H^5O^4)''' \\ H^2.M\end{matrix}\right\}O^3$
Acid dimetallic citrate	$\left.\begin{matrix}(C^6H^5O^4)''' \\ H.M^2\end{matrix}\right\}O^3$
Neutral trimetallic citrate	$\left.\begin{matrix}(C^6H^5O^4)''' \\ M^3\end{matrix}\right\}O^3$

Some of the citrates occur naturally, as citrate of calcium in onions and potatoes, and citrate of potassium in artichokes and potatoes. The alkaline citrates are very soluble; other citrates, as those of zinc, iron, cobalt and nickel are less so, while the citrates of the alkaline earths are insoluble. In the presence of soluble citrates, alkalis do not precipitate the salts of iron, manganese, or aluminium. The citrates decompose when heated to 230°C., forming empyreumatic products, which have not been investigated.

The following list includes all the principal citrates.

CITRATE OF ALUMINIUM.—Insoluble powder when it contains excess of metal; soluble gum when the acid is in excess.

CITRATE OF AMMONIUM. *Monammonic Citrate*, $C^6H^7(NH^4)O^7$.—Solution of citric acid, neutralised with ammonia, and then mixed with twice as much acid as it already contains, yields this salt by spontaneous evaporation in small triclinic prisms.

Diammonic Citrate, $C^6H^6(NH^4)^2O^7$, crystallises on the evaporation of a solution of citric acid which has been saturated by ammonia, in prisms which are anhydrous but deliquescent.

CITRATES OF BARIUM. *Tribarytic Citrate*, $C^6H^5Ba^3O^7$.—Citric acid added to excess of baryta-water throws down flakes which become somewhat crystalline. White powder; dried in the cold, it contains water of crystallisation, which it gives off completely at 200° C.

Monobarytic Citrate?—Obtained as a gummy mass by evaporating a solution of barytic citrate in citric acid.

A crystalline citrate of barium which, dried at 160° C., has the formula $C^{12}H^{11}Ba^5O^{14}$, is obtained by adding tribarytic citrate to a boiling transparent mixture of citric acid and chloride of barium, as long as the resulting precipitate redissolves, and then allowing the mixture to cool. It appears to be a double salt of tribarytic and dibarytic citrate.

Citrate of sodium is precipitated only by a large excess of chloride of barium: hence citrate of barium must be somewhat soluble in citrate of sodium.

CITRATE OF CADMIUM.—Crystalline sparingly soluble salt.

CITRATES OF CALCIUM. *Tricalcic Citrate*, $C^6H^5Ca^3O^7 + 2H^2O$.—When chloride of calcium is gradually added to a solution of citrate of sodium, the precipitate at first formed redissolves, but when agitated, it suddenly forms a magma which becomes crystalline on the application of heat. The salt is more soluble in cold than in hot water, so that a cold solution becomes turbid on being boiled.

Dicalcic Citrate, $C^6H^6Ca^2O^7 + H^2O$.—Obtained in shining laminæ by dissolving the preceding compound in excess of citric acid, and evaporating the solution.

Citrate of Cerium.—White insoluble powder, obtained by double decomposition of alkaline citrates and cerous salts.

Citrate of Cobalt, $C^6H^5Co^3O^7 + 7H^2O$.—The solution of carbonate of cobalt in warm citric acid, solidifies on cooling, after adequate evaporation, to a rose-coloured magma, which dries up to a powder of the same colour.

Cupric Citrate.—Obtained in microscopic rhombohedra by heating a solution of cupric acetate with citric acid. The formula is $C^6H^5Cu^3O^7.CuHO + H^2O$.

Citrates of Iron. *Ferrous Citrate.*—Alcohol precipitates white flakes of triferrous citrate from a clear solution of iron in citric acid.

Ferric Citrate.—Freshly precipitated hydrated ferric oxide dissolves in warm aqueous citric acid, forming a reddish-brown liquid which on evaporation leaves a light-brown film. It is administered medicinally under this form. Ferrocyanide of potassium does not precipitate an acid solution of ferric citrate, but forms a blue liquid which is decolorised by ammonia.

Ammonio-ferric Citrate. (Ammonio-citrate of iron.)—When 2 pts. of freshly precipitated ferric hydrate are dissolved in 3 pts. of citric acid, the solution saturated with ammonia leaves on evaporation a greenish-yellow mass, insoluble in strong alcohol, but soluble in alcohol of 40 per cent.

Citrate of Lithium.—Amorphous, limpid, hard mass.

Citrates of Lead. *Triplumbic Citrate*, $C^6H^5Pb^3O^7$ (at 120° C.), is best obtained by precipitating an alcoholic solution of plumbic acetate with an alcoholic solution of citric acid, and washing the precipitate with alcohol; it is granular when hot solutions are employed.

Diplumbic Citrate. $C^6H^6Pb^2O^7 + H^2O$.—A solution of acetate of lead is added to a boiling dilute solution of citric acid as long as the precipitate redissolves. On evaporating the clear solution, the salt crystallises in small prisms. Ammonia dissolves this salt, and the solution afterwards deposits triplumbic citrate.

Tetrabasic Salt.—By digesting triplumbic citrate with ammonia, Berzelius obtained a heavy white powder, which had the formula $C^6H^5Pb^3O^7.PbHO$, or $C^{12}H^5Pb^3O^{11}.PbO + HO$). The triplumbic citrate digested with excess of subacetate of lead, gave an insoluble amorphous powder, which had the formula $C^6H^5Pb^3O^7.PbHO.Pb^2O$ (or $C^{12}H^5Pb^3O^{11}.3PbO + HO$). Heldt obtained a salt of the formula $2(C^6H^5Pb^3O^7.Pb^2O) + 3H^2O$, or $C^{12}H^5Pb^3O^{11}.2PbO + 3HO$, by digesting triplumbic citrate with ammonia for two days in a close vessel. Bulky, white, insoluble powder

Citrate of Magnesium. $C^6H^5Mg^3O^7 + 7H^2O$.—Carbonate of magnesium dissolves in citric acid to a solution which forms a thick magma when concentrated. Alcohol precipitates the salt from its aqueous solution.

This salt, evaporated with excess of citric acid, yields a gummy mass, which does not become crystalline.

When carbonate of magnesium is digested with disodic citrate, the filtered solution on evaporation leaves small crystalline groups, which contain sodium and magnesium.

Citrate of Manganese. $C^6H^6Mn^2O^7 + H^2O$.—Citrate of sodium does not precipitate manganous salts; but when carbonate of manganese is digested with citric acid, the above salt is obtained as a white insoluble crystalline powder.

Citrates of Mercury.—Citric acid precipitates from *mercurous* acetate, a white powder soluble in nitric acid.

Freshly precipitated *mercuric oxide* dissolves in hot citric acid, and the solution on cooling deposits a white powder, which is decomposed by water.

Citrate of Nickel. $C^6H^5Ni^3O^7 + 7H^2O$.—Oxide of nickel dissolves in citric acid to a green liquid, gradually changing into a green jelly, which on evaporation leaves an olive-green film, soluble in water but precipitated by alcohol.

Citrates of Potassium. *Tripotassic Citrate.* $C^6H^5K^3O^7 + H^2O$.—A solution of carbonate of potassium neutralised with citric acid, yields by spontaneous evaporation, transparent, stellate-grouped needles, very deliquescent, and insoluble in absolute alcohol. They lose their water of crystallisation at about 200° C.

Dipotassic Citrate. $C^6H^6K^2O^7$.—A solution of 2 pts. of citric acid neutralised with carbonate of potassium, and mixed with 1 pt. of citric acid, yields by evaporation an amorphous mass having a sour taste.

Monopotassic Citrate. $C^6H^7KO^7 + 2H^2O$.—1 pt. of citric acid is neutralised with potash, 1 pt. of citric acid added, and the mixture evaporated at 40° C. Large transparent prisms, permanent in the air, and having an agreeable sour taste. They melt in their water of crystallisation, and give off 13·8 per cent. of water, forming a viscous liquid, which solidifies on cooling to a concentric radiated mass of crystals, consisting of $C^6H^7KO^7$.

Ammonio-potassic Citrate. $C^6H^5K^2(NH^4)O^7$.—A solution of dipotassic citrate neutralised with ammonia, yields this salt, on evaporation, in transparent deliquescent prisms.

Potassio-antimonic Citrate.—1 pt. of citric acid is neutralised with potash; 1 pt. more of acid added; the mixture boiled for some time with trioxide of antimony, and the filtrate left to crystallise. White, shining, very hard prisms, grouped in tufts. They give off 6·7 per cent. of water at 190° C. May be regarded as a double molecule of tripotassic citrate, in which part of the potassium is replaced by the tribasic radicle, antimony: $C^{12}H^{10}(K^3Sb''')O^{14}$.

CITRATE OF SILVER. $C^6H^5Ag^3O^7$.—Citrate of potassium added to solution of nitrate of silver, throws down this salt as a heavy white powder, which crystallises from boiling water in white or yellowish needles. Deflagrates at a high temperature.

Argentous Salt.—The above salt heated to 100° C. in a current of hydrogen, is changed into a dark brown mass, which is a mixture of citric acid and triargentous citrate. Water extracts from this mass first citric acid, and then a small quantity of argentous salt with a red colour. This red solution heated to boiling, assumes a green and blue colour, then deposits metallic silver, and becomes decolorised.

CITRATES OF SODIUM. *Trisodic Citrate.* $2(C^6H^5Na^3O^7) + 11H^2O$.—When a solution of citric acid is saturated with soda, and the solution left to evaporate, large rhombic prisms are obtained of this composition. They quickly effloresce and are sparingly soluble in alcohol. At 100° C. 7 at. water are given off, and at 190°—200°, 4 at. more. A solution of this citrate evaporated at 60° C., yields monoclinic crystals containing only 2 at. water.

Disodic Citrate. $C^6H^6Na^2O^7.H^2O$.—Obtained like the corresponding potassium-salt. Prismatic, stellate-grouped crystals, which give off their water of crystallisation when dried over oil of vitriol.

Monosodic Citrate. $C^6H^7NaO^7 + H^2O$.—Obtained like the corresponding potassium-salt. A very concentrated solution left to evaporate in a warm place, solidifies to a mass of acicular crystals, and crystallises to the last drop.

Ammonio-sodic Citrate.—Confused crystalline crust.

Potassio-sodic Citrate. $C^6H^5Na^3O^7.C^6H^5K^3O^7 + 11H^2O$—Obtained by dissolving equivalent quantities of trisodic citrate and tripotassic citrate, and concentrating by evaporation. It is deposited after some days in radiate-grouped, lustrous needles.

CITRATE OF STRONTIUM.—Strontia-water is precipitated by citric acid in thick white flakes, which, after drying over oil of vitriol, have the composition $C^6H^5Sr^3O^7 + H^2O$. They lose their water of crystallisation at 210° C.

CITRATE OF ZINC. $C^5H^5Zn^3O^7 + H^2O$.—Carbonate of zinc dissolves readily in aqueous citric acid; on boiling, the salt is precipitated as a granular, crystalline powder. The aqueous solution of this salt mixed with a small quantity of citric acid, and evaporated at a gentle heat, deposits transparent crystals, which have the composition $C^6H^5Zn^3O^7.C^6H^6Zn^2O^7 + H^2O$.

Substitution-derivative of Citric Acid.

OXYCHLOROCITRIC ACID. $C^6H^6Cl^2O^6 = \left.\begin{matrix}(C^6H^5O^4)'''\\H^3\end{matrix}\right\}\begin{matrix}Cl^2\\O^2\end{matrix}$.—When pentachloride of phosphorus is mixed with dry citric acid, the mass becomes heated, liquefies, and then solidifies to a magma of crystals which consist of oxychlorocitric acid mixed with oxychloride of phosphorus. The latter is removed by digestion with disulphide of carbon, the mass is thrown on a filter, and washed with disulphide, then pressed between bibulous paper, and dried in a current of hot air. It forms colourless silky needles:

$$C^6H^8O^7 + \acute{P}Cl^5 = C^6H^6O^6Cl^2 + POCl^3.$$

In moist air or in water, this acid becomes heated and is converted into citric acid.

On heating it in a stream of dry air to 100° C., hydrochloric acid is liberated, and the residue consists of aconitic acid. Dry ammonia acts violently upon it, forming a black vesicular mass. In contact with aniline, the acid becomes strongly heated, and yields phenyl-aconitimide.

E. A.

CITRIC ACID, AMIDES OF. (Pebal, Ann. Ch. Pharm. lxxxii. 73; xcviii. 67.)—Of the amides of citric acid, bodies derived from ammonia by the replacement of hydrogen by the radicle citryl, only citramide is known; but many of the corresponding phenyl-compounds have been obtained by Pebal.

CITRAMIDE. $C^6H^{11}N^3O^4 = \left.\begin{matrix}(C^6H^5O^4)''' \\ H^3 \\ H^3\end{matrix}\right\}N^3$, is a crystalline compound, slightly soluble in water, obtained by the action of alcoholic ammonia on citrate of methyl or citrate of ethyl.

Phenylcitramide. Citranilide. $\left.\begin{matrix}(C^6H^5O^4)''' \\ (C^6H^5)^3 \\ H^3\end{matrix}\right\}N^3$, is obtained by the action of heat on triphenylamic citrate:

$$\underset{\text{Triphenylamic citrate.}}{C^6H^5(C^6H^8N)^3O^7} - 3H^2O = \underset{\text{Phenylcitramide.}}{C^{24}H^{23}N^3O^4}.$$

To prepare this body, the yellow powder left on heating triphenylamic citrate is dissolved in boiling alcohol, and the solution is decolorised by animal charcoal. On cooling, two sets of crystals are deposited, hexagonal plates and fine prisms. The former consist of phenylcitrimide, and are dissolved out by boiling with alkali, which does not perceptibly affect the phenylcitramide. Phenylcitramide is deposited from alcohol in colourless prisms, truncated longitudinarily, and with a nacreous lustre. Neutral to vegetable colours.

Phenylcitrimide. Citrobianil. $C^{18}N^2H^{16}O^4 = \left.\begin{matrix}(C^6H^5O^4)''' \\ (C^6H^5)^2 \\ H\end{matrix}\right\}N^2$, represents diphenylamic citrate *minus* 3 atoms of water:

$$\underset{\text{Diphenylamic citrate.}}{C^6H^6(C^6H^8N)^2O^7} - 3H^2O = \underset{\text{Phenylcitrimide.}}{C^{18}H^{16}N^2O^4}.$$

It is obtained in the preparation of phenylcitramide; also by heating phenylcitramic acid with phenylamine:

$$\underset{\text{Phenylcitramic acid.}}{C^{12}H^{11}NO^5} + \underset{\text{Phenylamine.}}{C^6H^7N} = \underset{\text{Phenylcitrimide.}}{C^{18}H^{16}N^2O^4} + H^2O.$$

Hexagonal plates, soluble in alcohol, and converted by boiling with ammonia into diphenylcitramic acid.

Phenylcitramic Acid. Citranilic Acid. $C^{12}H^{11}NO^5 = \left.\begin{matrix}N(C^6H^5)(C^6H^5O^4)''' \\ H\end{matrix}\right\}O$.—Obtained by the action of heat on monophenylamic citrate:

$$\underset{\text{Monophenylamic citrate.}}{C^6H^7(C^6H^8N)O^7} - 2H^2O = \underset{\text{Phenylcitramic acid.}}{C^{12}H^{11}NO^5}.$$

Monophenylamic citrate is heated to 140° — 150° C. as long as water is given off. On cooling, the residue becomes crystalline. It dissolves readily in water, and if excess of phenylamine has been avoided, it is deposited in small crystalline spherules, or in mamillary groups of small prisms. It has an acid reaction, and forms crystalline salts with silver and with aniline.

On treating it with pentachloride of phosphorus, hydrochloric acid is given off, and a liquid formed, which appears to contain *chloride of aconitanyl*, $C^{12}NH^8O^3.Cl$, as, when treated with water, it is resolved into hydrochloric acid and phenylaconitamic acid.

Diphenylcitramic Acid. Citrobianilic Acid. $C^{18}H^{18}N^2O^5$.—Obtained in the form of an ammonia-salt by boiling phenylcitrimide with ammonia. By adding hydrochloric acid to the solution, the acid is precipitated. Recrystallised from alcohol, it forms soft, concentrically-grouped, silky needles. It melts and gives off water at 150° C., and becomes reconverted into phenylcitrimide.

Diphenylcitramic acid contains the elements of diphenylamic citrate *minus* 2 at. water: $C^6H^6(C^6H^8N)^2O^7 - 2H^2O = C^{18}H^{18}N^2O^5$, and may be represented by the formula $\left.\begin{matrix}(C^6H^5)^2 \\ (C^6H^5O^4)''' \\ H^3\end{matrix}\right\}\begin{matrix}N^2 \\ O\end{matrix}$, derived from the mixed type $N^2H^6.H^2O$. E. A.

CITRIC ETHERS. The citric ethers represent citric acid in which one or more atoms of hydrogen are replaced by alcohol-radicles. Those in which one or two atoms of hydrogen are thus replaced have acid properties.

Citrate of Methyl. *Trimethylic Citrate.* $C^9H^{14}O^7 = \left.\begin{matrix}(C^6H^5O^4)'''\\(CH^3)^3\end{matrix}\right\}O^3$.—A solution of citric acid in wood-spirit is saturated with hydrochloric acid gas; on rectifying the mixture, chloride of methyl and the excess of wood-spirit pass off, and a colourless liquid distils over at about 90° C., which is citrate of methyl. After standing some time it crystallises. (Saint-Èvre, Compt. rend. xxi. 144.)

Monomethylcitric Acid, $\left.\begin{matrix}(C^6H^5O^4)'''\\H^2.CH^3\end{matrix}\right\}O^3$, and *Dimethylcitric acid*, $\left.\begin{matrix}(C^6H^5O^4)'''\\H.(CH^3)^2\end{matrix}\right\}O^3$, are both formed in the preparation of citrate of methyl. They have been but little examined. (Demondesir, Compt. rend. xxxiii. 227.)

Citrate of Ethyl. *Citric Ether.* $\left.\begin{matrix}(C^6H^5O^4)'''\\(C^2H^5)^3\end{matrix}\right\}O^3$. (Thénard, Mém. d'Arcueil, ii. 12.—Malaguti, Ann. Ch. Phys. lxiii. 197.—Dumas, Compt. rend. viii. 528.—Marchand, J. pr. Chem. xx. 318.—Heldt, Ann. Ch. Pharm. xlvii. 57.—Demondesir, *loc. cit.*)—This body is formed by distilling a mixture of sulphuric acid, citric acid, and alcohol; but the best method of preparing it, according to Demondesir, is as follows: A solution of citric acid in alcohol is saturated with hydrochloric acid gas, the liquid neutralised with carbonate of soda, and agitated with common ether, which dissolves out the citric ether. On evaporating the ethereal solution, citric ether is left as an oily, yellowish, transparent liquid, with an odour resembling olive oil. Its specific gravity is 1·142. It is very soluble in alcohol and in ether. It boils at 280° C., but decomposes—probably into aconitic or citraconic ether. It is decomposed by free alkalis into citrates and free alcohol. With ammonia it yields, besides citramide, several products which have not been examined. E. A.

CITRIDIC ACID. Syn. with Aconitic Acid.

CITRILENE. See Citrene.

CITRINE. A glassy variety of quartz having a wine-yellow colour.

CITRINS. *Citroglycerins. Citrates of Glyceryl.* (van Bemmelen, J. pr. Chem. lxix. 84.)—Two of these compounds have been obtained by heating citric acid with glycerin.

Neutral Citrate of Glyceryl, $C^9H^{10}O^7 = \left.\begin{matrix}(C^6H^5O^4)'''\\(C^3H^5)'''\end{matrix}\right\}O^3$, is prepared by heating citric acid with a slight excess of glycerin to 160°—170° C. for twenty hours. Water then escapes, and there remains a hard, light yellow, transparent mass, from which the pure product may be obtained by boiling out the excess of glycerin with alcohol. It is difficult to pulverise; insoluble in water, alcohol, and ether. Hydrochloric acid dissolves it gradually with aid of heat; sulphuric acid immediately, with blackening. It dissolves gradually in cold potash-ley, and when boiled with bases, is quickly resolved into citric acid and glycerin. The formation of the compound is represented by the equation:

$$\underset{\text{Citric acid.}}{C^6H^8O^7} + \underset{\text{Glycerin.}}{C^3H^8O^3} = C^9H^{10}O^7 + 3H^2O.$$

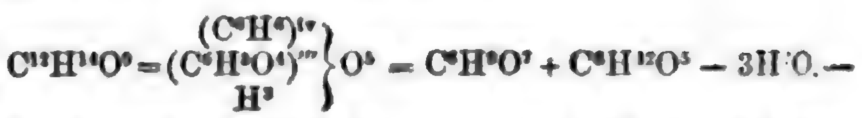
Basic Citrate of Glyceryl. Citrodiglyceride, $C^{12}H^{18}O^{10} = C^9H^{10}O^7.C^3H^8O^3$, may be regarded as a double molecule of glycerin $\left(\left.\begin{matrix}C^6H^{10}\\H^6\end{matrix}\right\}O^6\right)$, in which 3 at. hydrogen are replaced by citryl, that is to say, as $\left.\begin{matrix}(C^6H^{10})^{vi}\\(C^6H^5O^4)'''\\H^3\end{matrix}\right\}O^6$.—Obtained like the preceding, by heating citric acid with a double quantity of glycerin. The mass melts at 100° C., and the transformation is completed between 160° and 170°. The product purified by boiling with alcohol, is yellowish-brown, somewhat darker and less hard than the neutral compound, which, however, it resembles in other respects.

CITROCERIC and **CITROLIC ACIDS.** Two acids said to be contained in the sediment of lemon and bergamot oils; the former is waxy, the latter oily. (Mylius, Arch. Pharm. xxxii. 28.)

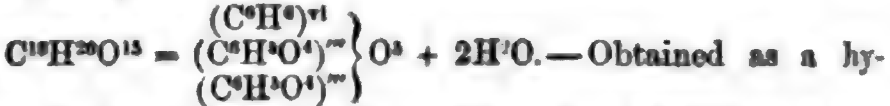
CITRODIANIL. Syn. with Phenylcitrimide (p. 998).

CITROGLYCERIN. See Citrins.

CITROMANNITANS. (v. Bemmelen, Jahresber. f. Chem. 1858, p. 435.)—This term is applied to two compounds derived from mannite in the same manner as the citrins are derived from glycerin. They are formed by heating citric acid with mannite in proper proportion to between 130° and 140° C., combination then taking place, attended with elimination of water.



Monocitromannitan. $C^{12}H^{14}O^{9} = \left.\begin{matrix}(C^{6}H^{8})^{iv}\\(C^{6}H^{5}O^{4})'''\\H^{3}\end{matrix}\right\}O^{5} = C^{6}H^{8}O^{7} + C^{6}H^{12}O^{5} - 3H^{2}O$.— A hard, light yellow, tasteless substance, insoluble in cold water, alcohol, and ether, decomposed by long boiling with water or alcohol, also by alkalis. Between 170° and 180° C. it turns brown and decomposes.



Dicitromannitan. $C^{18}H^{20}O^{15} = \left.\begin{matrix}(C^{6}H^{8})^{vi}\\(C^{6}H^{5}O^{4})'''\\(C^{6}H^{5}O^{4})'''\end{matrix}\right\}O^{5} + 2H^{2}O$.—Obtained as a hydrate by heating 2 at. citric acid and 1 at. mannite for some time to between 140° and 150° C. The product is a dry, hard, light yellow mass, which has no acid reaction, dissolves in water only after long boiling, is easily decomposed by alkalis, and does not give off water without decomposition when heated.

CITRON, OIL OF. See CITRUS MEDICA (p. 1004).

CITRONYL. The name applied by Blanchet and Sell to that constituent of lemon-oil, which forms a crystallisable compound with hydrochloric acid (p. 1004). It is sometimes also applied to the triatomic radicle of citric acid.

CITROPTENE. The camphor or stearoptene of lemon-oil (p. 1004).

CITRUS. A genus of plants belonging to the natural order *Aurantiaceæ*, and including the orange, lemon, citron, shaddock, &c. They all produce juicy fruits containing citric acid, and enclosed in a thick fleshy rind containing volatile oils, which are isomeric with oil of turpentine, but differ from one another in odour, density, action on polarised light, &c.

CITRUS AURANTIUM. The *Sweet Orange.*—The rind of this fruit contains a volatile oil, *Oil of orange-peel, Oleum corticum aurantiorum*, which may be extracted by pressure or by distillation with water. It has the same composition and vapour-density as oil of lemon. Specific gravity in the liquid state 0·83—0·89. Boiling point 180° C. It is neutral, and has an agreeable odour. Optical rotatory power, 125·6°—127·4° to the right. It dissolves completely in absolute alcohol, and with turbidity in 7—10 pts. alcohol of specific gravity 0·85. It unites with hydrochloric acid, forming a liquid compound, $C^{10}H^{16}.HCl$, and a solid compound, $C^{10}H^{16}.2HCl$, which melts at 50° C. (Gm. xiv. 306.)

Orange-peel also contains, especially in the unripe state, a bitter principle called **Aurantiin** or **Hesperidin** (*q. v.*)

The juice of the orange contains citric and malic acids, partly free, partly combined with bases. The juices of sweet oranges likewise contains grape-sugar or cane-sugar; the grape-sugar predominates in the unripe state, but does not sensibly increase in quantity as the fruit ripens, while the amount of cane-sugar increases, both absolutely and relatively to the weight of the orange, the juice, and the solid constituents (Berthelot and Buignet, Compt. rend. li. 1094). 100 pts. of oranges contain 4·2 per cent. cane-sugar, 4·3 grape-sugar, and 0·45 free acid (Buignet, Ann. Ch. Phys. lxi. 233). The pips of the orange contain a bitter substance, which appears to be identical with the limonin of lemon-pips.

The flowers of the orange contain a very fragrant volatile oil, called *Oil of Neroli, Oleum florum naphæ s. neroli*, which is obtained by distilling the flowers with water. When recently prepared, it is nearly colourless, but reddens quickly on exposure to light. According to Soubeiran and Capitaine, it is composed of two oils, one easily soluble in water and very fragrant, while the other is sparingly soluble and has a less agreeable odour; the latter floats on the watery distillate, and is easily separated. The more fragrant oil may be extracted from the watery distillate (*orange-flower water*) by means of ether. It is reddened by *sulphuric acid*, and communicates this property to the entire essence. *Nitric acid* colours the oil brown. According to Döbereiner, oil of neroli produces a peculiar acid in contact with *platinum-black*. Oil of neroli dissolves clearly in 1—3 pts. *alcohol* of specific gravity 0·85, and with turbidity in a larger quantity. According to Boullay and Plisson, alcohol of 90 per cent. separates from oil of neroli a solid substance, neroli-camphor, melting at 50° C.; insoluble in water, sparingly soluble in boiling absolute alcohol; very soluble in ether; it appears to contain 83·76 per cent. C, 15·09 H, and 1·15 O; probably a hydrocarbon when pure. (Gm. xiv. 386; Gerh. iii. 639.)

The leaves of the orange yield a watery infusion characterised by a bitter aromatic taste.

The following table exhibits the composition of the ash of various parts of the orange-tree: —

Ash of Orange-tree.

	Rowney and Blow.					Richardson.
	Root.	Stem.	Leaves.	Fruit.	Pips.	Fruit.
Ash, per cent. . .	4·48	2·74	13·7	3·94	3·3	—

Ferric phosphate . .	—	—	—	—	—	1·7

Citrus Bergamia. *The Bergamot.*—The rind yields by pressure a volatile oil, $C^{10}H^{16}$, which deposits by keeping, a solid camphor called bergaptene, having the composition C^3H^2O. (See Bergamot, Oil of, p. 580.)

Citrus Bigaradia. The *Bigarade* or *Bitter Orange* (*Bigaradier* of the French, *Melangolo* of the Italians).—The rind of the fruit of this plant yields by pressure a volatile oil, $C^{10}H^{16}$, commonly called *Oil* or *Essence of Mandarin* (though the mandarin orange is a variety of *Citrus aurantium*). After filtration, it has a pale yellowish colour, but after rectification it is colourless, clear, and mobile. Specific gravity, 0·852 at 10° C., 0·8517 at 12°. Boiling point 178°. It has an agreeable odour, different from that of lemon or orange-oil, and a not unpleasant taste, like that of orange-oil. Optical rotatory power 85·5° to the right. It is insoluble in *water*, but soluble in 10 pts. of *alcohol*, also in *ether* and *glacial acetic acid*, and in all proportions in *sulphide of carbon*. It dissolves *bromine*, *iodine*, *phosphorus*, *sulphur*, *oils* both fixed and volatile, *wax*, and *resins*. With *hydrochloric acid* it forms a crystalline compound containing $C^{10}H^{16}.2HCl$. Cold *nitric acid* colours it faintly yellow; hot nitric acid decomposes it, with evolution of nitrous fumes, and the mixture, on addition of water, deposits a nearly solid mass. With *alcoholic nitric acid*, it forms a crystalline mass, probably a hydrate. It is reddened by cold *sulphuric acid*, and carbonised when heated therewith. (S. de Luca, Compt. rend. xlv. 904.—Gm. xiv. 304.)

The Seville bigarade, or Seville orange, is much used for the preparation of bitter tinctures and of candied orange-peel. The bitter aromatic principle is a powerful tonic, and gives its flavour to the liquid called Curaçoa.

Citrus Limetta. The *Lime.*—The rinds when torn and pressed, or distilled with water, yield an oil which resembles oil of lemon, and when treated with sulphuric acid and chromate of potassium, forms limettic acid, $C^{11}H^8O^6$. (Gm. *loc. cit.*)

Citrus Limonum. The *Lemon.*—Regarded by many writers as a variety of *Citrus medica.*

Lemon-juice contains free citric acid, and is used for the preparation of that acid (p. 902), also mucus, vegetable albumin, and sugar; according to Buignet (Ann. Ch. Phys. [3] lxi. 233), 100 pts. of it contain 1·1 grape-sugar, 0·4 cane-sugar, and 4·7 free acid. The nitrogenous matter causes it to putrefy easily, whence it acquires an unpleasant smell and taste; to prevent this change, it is often kept in bottles, with a layer of oil on its surface.

According to Witt (Chem. Soc. Qu. J. vii. 44), lemon-juice contains from 0·2 to 0·5 per cent. ash, consisting in 100 pts. of 44·3 per cent. potash, 2·1 soda, 7·6 lime, 3·3 magnesia, 12·5 sulphuric anhydride, 19·7 carbonic anhydride, 7·6 phosphoric anhydride, 1·0 ferric phosphate, 1·2 chlorine, and 0·6 silica.

Lemon-pips contain in the nucleus, citrate of potassium, a fatty non-drying oil, a tallow-like fat, a bitter principle called *limonin*, together with other constituents.

In the ash of lemon-pips, Souchay (J. pr. Chem. xxxviii. 25) found 33·2 per cent. potash, 3·5 soda, 12·6 lime, 8·5 magnesia, 0·2 ferric oxide, 34·1 phosphoric anhydride, 3·2 sulphuric anhydride, 2·3 chloride of sodium, and 0·3 silica.

Oil of Lemon.—Lemon-peel contains a volatile oil, called *Oil of lemon*, *Oleum citri*, which is extracted by pressure or by distillation with water. This oil is composed for the most part of a hydrocarbon isomeric with oil of turpentine, $C^{10}H^{16}$, and having the same vapour-density (4·81—4·87). It is neutral, and has an agreeable odour. Specific gravity in the liquid state, 0·84—0·86 (Zeller). Boiling point 173° C. (Blanchet and Sell); 176·1° (Brix). It volatilises in the air at ordinary temperatures without leaving a perceptible grease-spot, provided it has not become resinous by oxidation. It deflects the plane of polarisation of light to the right.

Oil of lemon, obtained as above, is, however, a mixture of two hydrocarbons, having the same composition, but differing in optical rotatory power and in their behaviour with hydrochloric acid. These two hydrocarbons may be separated by distilling the oil in vacuo. The first portions collected at 55° C. have a density of 0·8514 at 15° C., rotatory power = + 56·4°, and when saturated with hydrochloric acid gas, yield a solid and a liquid dihydrochlorate. The following portions collected at about 80° C. have a specific gravity of 0·8506 at 15°, rotatory power = + 72·5°, and are almost wholly transformed by hydrochloric acid into a solid dihydrochlorate; they likewise contain a sensible amount of oxidised oils. (Berthelot.)

Oil of lemon dissolves sparingly in *water*, in 7·14 pts. *alcohol* of specific gravity 0·8317, in 10 pts. alcohol of specific gravity 0·85, in any quantity of absolute alcohol, and mixes readily with *oils* both fixed and volatile. It dissolves *sulphur* and *phosphorus*, also *resins* and other bodies.

Oil of lemon when exposed to *air* and *light*, absorbs oxygen, with formation of ozone, becoming at the same time darker and more viscid, and forming a small quantity of carbonic acid; according to Aschoff, the crude, but not the rectified oil, turns acid on exposure to the air, forming acetic acid and lemon-camphor. At a *red heat*, the oil is decomposed, with formation of tar and charcoal. *Chlorine* decomposes it; cotton soaked in the oil and immersed in chlorine gas becomes charred on the surface, but does not take fire. When *bromine* is covered with a layer of water, the water with oil of lemon, and the whole carefully mixed, the bromine becomes decolorised without explosion, and a brominated oil is formed, 1 pt. of rectified lemon-oil taking up 2·28 pts. and 1 pt. of the crude oil, 2·4 to 2·5 pts. of bromine (G. Williams, Chem. Gaz. 1853, p. 365). *Iodine* decomposes oil of lemon with rise of temperature. Strong *nitric acid* turns it brown and resinises it; alcoholic nitric acid converts it into a hydrate. With strong *sulphuric acid*, it assumes a yellowish brown colour, and yields terebene and colophene; similarly when distilled with *phosphoric anhydride*. Lemon-oil dropped into a large quantity of oil of vitriol is said to yield sulphoterebic acid (Gerhardt). *Potassium* eliminates hydrogen from lemon-oil, slowly at common temperatures, more quickly when heated, acquiring at the same time a brown colour; after repeated distillation over potassium, however, the oil undergoes no further alteration, and then possesses a finer odour than before. *Hydrate of potassium* separates from oil of lemon a brown substance, the oil thereby acquiring a stronger and more agreeable odour.

Oil of lemon is largely used in perfumery; it should not be dark coloured or viscid or leave a perceptible stain on paper. It is often adulterated with cheaper oils, such as oil of turpentine or oil of lavender, and sometimes with alcohol. The latter adulteration may be detected by agitation with water, the pure oil then exhibiting no perceptible diminution of volume. The pure oil is also coloured brownish by acid chromate of potassium, whereas if it contains alcohol, it turns greenish.

The admixture of cheaper oils may generally be detected by the odour. Oil of turpentine may also be detected in oil of lemon by its different behaviour to polarised light, especially when heated, the molecular constitution of oil of lemon being much less altered by heat than that of oil of turpentine. The rotatory power of the suspected oil is first to be determined at the ordinary temperature, and again after the oil has been heated to 300° C. for an hour or two. If the oil is pure, no change will be perceived, but if oil of turpentine is present, especially the French kind, which is lævo-rotatory, the dextro-rotatory power of the oil will be considerably increased by the heating.

Hydrate of Lemon-oil is a crystalline substance isomeric with hydrate of turpentine-oil, $C^{10}H^{16}.2H^2O$, obtained by mixing 1 pt. of lemon-oil with $\frac{3}{4}$ pt. alcohol, of specific gravity 0·85, and $\frac{1}{4}$ pt. ordinary nitric acid, and leaving the mixture to itself for some time. (Deville.)

Hydrochlorates of Lemon-oil.—These compounds are formed by saturating the oil with hydrochloric acid gas, also by treating the oil with the aqueous acid. The compound formed in largest quantity is the *dihydrochlorate*, $C^{10}H^{16}.2HCl$, of which there is a solid and a liquid modification, the latter being produced chiefly from the more volatile, the former from the less volatile portion of the oil. (Berthelot, *vid. sup.*)

Monohydrochlorate. $C^{10}H^{16}.HCl$.—This compound is produced by saturating a solution of lemon-oil in acetic acid or alcoholic sulphuric acid, with hydrochloric acid gas, and collecting the few crystals which separate, rarely, however, and only under peculiar circumstances. It appears also to be present in small quantity in the portion of lemon-oil which remains liquid after the separation of the solid dihydrochlorate. The crystals melt at 100° C., and volatilise without decomposition at higher temperatures.

Dihydrochlorate. $C^{10}H^{16}.2HCl$.—The solid modification of this compound is obtained by passing dry hydrochloric acid gas to saturation into rectified and dehydrated oil of lemon well cooled, separating the resulting crystals from the mother-liquor, pressing them repeatedly between paper, washing them with cold alcohol, recrystallising from hot alcohol, drying in the air, afterwards in vacuo or over oil of vitriol, and once more crystallising from ether (Blanchet and Sell). It forms right four-sided prisms or laminæ, heavier than water; has an aromatic odour; is insoluble in water, soluble at 14° C. in 5·88 pts. of alcohol of specific gravity 0·806; and separates from the solution, on addition of water, in crystalline laminæ. On evaporating the alcoholic solution, partial decomposition takes place. The crystals are also soluble in oils both fixed and volatile. The compound is optically inactive, melts at 43° or 44° C., and solidifies crystalline on cooling; it sublimes at 50° C. without decomposition, boils at 142° (Cahours), at 162° (Blanchet and Sell), with partial decomposition, hydrochloric acid escaping and an oil passing over, which does not solidify till cooled to 20° C. The crystals burn with difficulty when heated in the air. *Chlorine-gas* converts the fused compound, with rise of temperature, into a chlorinated compound, $C^{10}(H^{14}Cl^{2}).2HCl$, Laurent's *hydrochlorate de chlorocitrenèse.*

Dihydrochlorate of lemon-oil is decomposed by *silver* and *mercurous salts* in the cold, not by *oxide of lead*, even when heated. *Nitric acid* does not act upon it in the cold, but decomposes it when heated, with evolution of nitrous acid. *Strong sulphuric acid* decomposes it, separating hydrochloric acid. *Potassium* decomposes it, with separation of lemon-oil; if heat be applied, citrene (p. 992) is produced. The same product is obtained by repeated distillation of the compound with potash or lime, or by the action of those bases at high temperatures.

The liquid dihydrochlorate, called also *hydrochlorate of citrilene* and *hydrochlorate of citryl*, is contained in the mother-liquor of the preceding compound, and may be obtained pure by cooling the mother-liquor to −10° C. to separate the remaining quantity of the solid compound, and filtering through a mixture of chalk and animal charcoal, to remove free acid and colouring matter. It is a mobile oil, optically inactive, soluble in alcohol, and precipitated from the solution by water, with loss of hydrochloric acid. By treatment with hydrochloric acid gas, it is converted into a crystalline mass, which dissolves in alcohol, but separates therefrom, not in crystals, but in the form of a heavy oil, a small quantity remaining in solution.

Lemon-camphor or *Citroptene.*—A solid substance produced from lemon-oil by oxidation. It is formed when the oil is kept for some time in half-filled bottles, partly separating in the solid state, while the rest remains dissolved, and may be separated by rectifying the oil. It forms colourless volatile crystals, which smell like oil of lemon, have a sharp pungent taste, are neutral, insoluble in cold water, but very soluble in hot water, to which they impart a decided dichroïsm. It is soluble also in alcohol and ether, the hot saturated solutions solidifying on cooling. The compound melts at 46° C. (Mulder), above 100° (Berthelot), boils at a temperature above 100°, and distils in oil-drops, which solidify in the crystalline form; it may also be sublimed. When thrown on red-hot coals, it volatilises without taking fire. It dissolves in *sulphuric acid* with red colour and peculiar aromatic odour, and water precipitates from the solution a white resinous substance, which is insoluble in water, and does not melt at 100°. *Nitric acid* dissolves the camphor, with decomposition at common temperatures, but gives off nitrous acid when heated with it. The camphor does not absorb *hydrochloric acid.*

The composition of lemon-camphor is not known with certainty. According to Mulder, it contains 54·8 per cent. C, 9·2 H, and 36·0 O; according to Berthelot, 58·0 C, 7·5 H, and 34·5 O.

The term lemon-camphor is likewise applied to two other compounds, viz. the solid dihydrochlorate of lemon-oil, and the hydrate formed by the action of alcoholic nitric acid on the same oil.

CITRUS LUMIA. The *Sweet Lemon.*—This plant, which grows abundantly in Calabria and Sicily, yields a fruit very much like the common lemon. The rind yields by pressure a volatile oil, the greater part of which distils between 180° and 190° C. yielding a colourless limpid liquid.

The portion boiling at 180° is isomeric with oil of turpentine, &c., and has a density of 0·853 at 18°. It possesses a dextro-rotatory power = 34° for the transition-tint.

It is slightly soluble in *alcohol*, very soluble in *ether* and in *sulphide of carbon*. It is resinised by strong *nitric acid*, and, like oil of lemon, yields a crystalline hydrate with alcoholic nitric acid. With *hydrochloric acid*, it forms a liquid and a crystalline compound; the latter, which has a peculiar odour and melts a low temperature, is a *dihydrochlorate*, $C^{10}H^{16}.2HCl$. (S. de Luca, Compt. rend. li. 258.)

Citrus Medica. The *Citron*. (*Citradier* of the French, *Cedro* or *Cedrato* of the Italians.)—The fruit of this species is usually large, warted and furrowed, with an extremely thick spongy rind and a subacid pulp. It is chiefly valued for the fragrance of the rind, from which a delicate sweetmeat is prepared. Two volatile oils used in perfumery are extracted from it, viz. *oil of citron* and *oil of cedra*. Both are highly fragrant, almost colourless, and lighter than water; they are distinguished by their odour, that of oil of cedra partaking of the character of oil of bergamot. The two oils are often confounded by pharmaceutical writers. They appear to be obtained by distillation, as they are free from mucilage. Both of them are *hydrocarbons* isomeric with oil of turpentine. (Pereira, *Materia Medica*, 3rd ed. 1853, ii. 2032.)

CITRYL. This name is applied to the triatomic radicle, $C^6H^5O^4$, of citric acid, &c.; also by Blanchet and Sell to that portion of lemon-oil which forms a liquid compound with hydrochloric acid (p. 1002).

Chloride of citryl $(C^6H^5O^4)'''Cl^3$, appears to be formed, together with oxychlorocitric acid and chloride of aconityl, when citric acid is heated with pentachloride of phosphorus (p. 997), inasmuch as the mother-liquor which remains after the oxychlorocitric acid has crystallised out, yields, on addition of water, both citric and aconitic acids. (Pebal.)

The following is a list of the compounds of citryl described in preceding articles $[C^6H^5O^4 = Ci]$.

Chloride of Citryl . . .	$Ci'''Cl^3$	Citrate, diglyceric .	$\left.\begin{matrix}Ci'''\\2(C^3H^5)'''\\H^3\end{matrix}\right\}O^6$
Citric acid	$\left.\begin{matrix}Ci'''\\H^3\end{matrix}\right\}O^3$	Citromannitan . . .	$\left.\begin{matrix}Ci'''\\(C^6H^8)^{iv}\\H^3\end{matrix}\right\}O^3$
Citrates, monometallic . .	$\left.\begin{matrix}Ci'''\\H^2M\end{matrix}\right\}O^3$	Dicitromannitan . . .	$\left.\begin{matrix}Ci'''\\Ci'''\\(C^6H^6)^{iv}\end{matrix}\right\}O^3$
Citrates, dimetallic . . .	$\left.\begin{matrix}Ci'''\\HM^2\end{matrix}\right\}O^3$	Citramide	$\left.\begin{matrix}Ci'''\\H^3\\H^3\end{matrix}\right\}N^3$
Citrates, trimetallic . .	$\left.\begin{matrix}Ci'''\\M^3\end{matrix}\right\}O^3$	Phenylcitramide . .	$\left.\begin{matrix}Ci'''\\(C^6H^5)^3\\H^3\end{matrix}\right\}N^3$
Citrate, monomethylic . .	$\left.\begin{matrix}Ci'''\\CH^3\\H^2\end{matrix}\right\}O^3$	Phenylcitrimide . .	$\left.\begin{matrix}Ci'''\\(C^6H^5)^2\\H\end{matrix}\right\}N^3$
Citrate, dimethylic . .	$\left.\begin{matrix}Ci'''\\(CH^3)^2\\H\end{matrix}\right\}O^3$	Phenylcitramic acid . .	$\left.\begin{matrix}C^6H^5\\Ci'''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$
Citrate, trimethylic . .	$\left.\begin{matrix}Ci'''\\(CH^3)^3\end{matrix}\right\}O^3$	Diphinylcitramic acid . .	$\left.\begin{matrix}(C^6H^5)^2\\Ci'''\\H^3\end{matrix}\right\}\begin{matrix}N^2\\O\end{matrix}$
Citrate, triethylic . . .	$\left.\begin{matrix}Ci'''\\(C^2H^5)^3\end{matrix}\right\}O^3$		
Citrate, monoglyceric .	$\left.\begin{matrix}Ci'''\\(C^3H^5)'''\end{matrix}\right\}O^3$		

CIVET. An odoriferous substance obtained from animals of the genus *Viverra* (Cuv.), viz. the *Viverra civetta* of North Africa, *V. zibetha*, found on the continent of Asia, from Arabia to Malabar, and *V. Rasse* of Java. It is contained in a pouch situated between the anus and organs of generation, and is voided by the animals against shrubs or stones. A better quality is, however, obtained by keeping the animals in confinement, and squeezing the pouch at certain intervals.

Good civet is of a clear yellowish or brownish colour, not fluid, nor hard, but about the consistence of butter or honey, and uniform throughout, of a very strong smell, resembling musk or ambergris; quite offensive when undiluted, but agreeable when only a small portion of civet is mixed with a large quantity of other substances.

Civet unites with oils, but not with alcohol.

Boutron-Charlard states, that in an unexceptionably good civet, semi-fluid, unctuous and yellow, he found free ammonia, stearin, oleïn, mucus, resin, volatile oil, yellow colouring substance, and salts. No benzoic acid could be detected in it. (J. Pharm. 1824, p. 537.)

CLARIFICATION. Clarification is the process of freeing a liquid from heterogeneous matter or feculencies; the term is, however, seldom applied to the mere mechanical process of straining, for which see FILTRATION.— Albumin, gelatin, acids, certain salts, lime, blood, and alcohol, serve in many cases to clarify fluids, which cannot be freed from their impurities by simple percolation. Albumin or gelatin, dissolved in a small portion of water, is commonly used for fining vinous liquors, as it inviscates the feculent matter, and gradually subsides with it to the bottom. Albumin in the form of white of egg or serum of blood is particularly used for fluids with which it will combine when cold, as syrups; as it is coagulated by the heat, and then rises in a scum with the dregs.—Heat alone clarifies some fluids, as the juices of plants, in which, however, the albumin they contain is probably the agent.—A couple of handfuls of marl, thrown into the press, will clarify cider, or water-cider.

Very finely divided precipitates, which remain for a long time suspended in pure water, may often be made to settle down, by adding a soluble salt, such as salammoniac, to the water. The same addition greatly facilitates the filtering and washing of precipitates, which otherwise stop up the pores of the filter.

CLASSIFICATION. The object of a classification of chemical substances is the arrangement of them in such a way that the position in the system of each substance may express its own chemical nature and the relation in which it stands to other substances. Hence it is easy to see that a system of classification, which should be perfect, relatively to any given stage in the development of the science, would be an epitome of the whole mass of chemical knowledge existing at the time. Hitherto but slight advances have been made towards establishing a theory of the causes or essential nature of chemical action; our so-called chemical theories are, for the most part, attempts to express the mutual relations of a greater or lesser number of chemical substances; in reality, therefore, they are more or less comprehensive schemes of classification. A general system of chemical classification ought to embrace the fundamental principles of all such partial systems, so as to show the real nature and relative value of each: it ought, in fact, to be a general expression of these theories in much the same sense that they are general expressions of chemical facts. A discussion of the bases upon which a comprehensive classification is to be founded becomes therefore a discussion of chemical theories in general; and in this article we shall endeavour to set forth clearly those general results of chemical research, by reference to which the true value of all chemical theories must, in the present state of the science, be tested, and which must for the present, be taken as the foundation for any attempt at chemical classification, rather than to construct a detailed scheme of classification in which each individual substance should find its place.

A collection of complex objects can always be classified in several different ways, according as this or that quality is regarded as the most important. In the case of chemical substances, two causes are always at work to bring about changes of the point of view from which they are regarded with reference to their classification. In the first place, the number of objects to be classified is continually increasing through the discovery of new substances; and, in the second place, the finding out of new qualities in the bodies already known, tends continually to modify their apparent relations to each other. Hence it is not surprising that, instead of our being able to trace, in the history of chemistry, the gradual extension of one fundamental scheme of classification, we should find that the principles upon which it has been attempted to classify chemical substances have been gradually, but from time to time almost completely changed as the science has advanced. It is not necessary to consider here what these changes have been; we have only referred to their occurrence, in order to draw attention to the fact, that the most perfect classification which it is possible even now to give, can of necessity be nothing more than a representation of the results of chemical labour, as they appear viewed from the point which the science has now reached, and that it must hereafter be absorbed in some more general system, if it be not entirely set aside.

All chemical substances belong to one of two classes: namely, elements or simple bodies, and compound bodies. The chemical definition of an element is — a body which cannot be decomposed or shown to contain matter of more than one kind; compound bodies, on the other hand, are such as are made up of, or can be decomposed into, two or more distinct kinds of matter. For instance, water can be shown to contain two kinds of matter, called respectively oxygen and hydrogen; sugar can similarly be proved to be made up of oxygen, hydrogen and carbon; water and sugar are therefore both of them compound bodies; but neither oxygen, hydrogen, nor carbon can, by any analytical or *breaking-up* process, be made to yield anything else than oxygen, hydrogen, or carbon, respectively; these three bodies are therefore in a chemical sense, elements. It will be seen that the chemical idea of an elementary body does not by any means imply the absolute simplicity of the so-called elements; it may be that these bodies are compounds which, as yet, have resisted all attempts to decompose them, but which are capable of being decomposed by processes hitherto unknown. Nevertheless, if it should at some future time be shown that all our present elements are in reality compound bodies, the definition of elements as bodies which cannot be chemically decomposed would still hold good, though it would then be applicable to a new set of substances.

In the further classification of elementary and compound bodies, it is impossible to separate the consideration of one of these classes from that of the other; for the chemical nature of an elementary body can only be known by the study of the combinations which it forms; and the properties of every compound body are determined by those of the elements of which it is composed.

There are especially two points to be considered in reference to the relation in which the various elements stand to the compounds which they form: first, the atomic proportion in which they combine together; second, the chemical nature or function of the bodies into whose composition they enter. Considering them first in the former relation, we find that there are a certain number which are distinguished from all the rest by the simplicity of the proportion in which they unite with each other. To this class of elements belong hydrogen ($H = 1$), chlorine ($Cl = 35{\cdot}5$), bromine ($Br = 80$), iodine ($I = 127$), potassium ($K = 39$), sodium ($Na = 23$), lithium ($Li = 7$), rubidium ($Rb = 85{\cdot}4$), cæsium ($Cs = 133$), silver ($Ag = 108$).* They combine together usually in the proportion of one atom to one atom (see ATOMIC WEIGHTS), and but few compounds are known which contain more than two of these elements, unless an element of some other class be also present. Trichloride of iodine, ICl^3 †, and the supposed chloride of bromine, $BrCl^5$, are perhaps the only exceptions to the former of these rules, and the substances which form an exception to the second are all crystallised salts formed by the molecular union of normal binary compounds, such as NaCl and AgCl. These bodies cannot be proved to exist, except in the crystallised state, and the chemical properties of their two constituents are not modified to the extent which usually accompanies true chemical combination; hence it is probable that they are not true chemical individuals, but physical aggregates of entire molecules, analogous to salts containing water of crystallisation. Another property of the elements of this class, closely allied to the first that was mentioned, is that the proportion by volume in which those of them which can be measured in the gaseous state unite, is 1 : 1.

For reasons that will be further dwelt upon in the sequel, the elements of this class are termed *monatomic* elements; the remainder are termed *polyatomic* elements and are divisible into:

1. *Diatomic Elements.*—These are: oxygen ($O = 16$), sulphur ($S = 32$), selenium ($Se = 80$), tellurium ($Te = 128$), magnesium ($Mg = 24$), zinc ($Zn = 65$), cadmium, ($Cd = 112$), mercury ($Hg = 200$), calcium ($Ca = 40$), strontium ($Sr = 88$), barium ($Ba = 137$), platinum ($Pt = 98{\cdot}5$), and perhaps others. The elements of this class combine either two or more together and in very various proportions, *e. g.* ZnO, ZnS, SO^2, SO^3, CaS^5, Ba^2SO, $BaSO^2$, $BaSO^3$, $BaSO^4$, BaS^2O^3, BaS^2O^6, BaS^4O^6. They combine with the monatomic elements in the proportion of one atom or volume to two, forming compounds of which one molecule occupies twice the volume of the diatomic atom it contains, and the same volume as the two monatomic atoms: *e. g.* H^2O, Cl^2O, ClHO, KHS, &c. When more than one atom of a diatomic element enters into combination with one or more monatomic elements, the ratio of combination is sometimes much more complex: *e. g.* H^2O^2, Cl^2S^2, Cl^2SO, Cl^2SO^2, $KHSO^3$, $KHSO^4$, &c.‡

---

* Fluorine is usually regarded as also belonging to this class, being associated with chlorine, bromine, and iodine; its known analogies to these bodies are not, however, either close or numerous, while its great tendency to unite at the same time with two different metals, or with hydrogen and a metal, seems to indicate that it ought rather to be placed in the next class of elements ($F = 38$, hydrofluoric acid $= FH^2$).

† This is not the only case in which iodine forms a compound of greater complexity than other members of the same class: for instance, iodic acid forms anhydro-salts, which are without analogues among the compounds of the other monatomic elements.

‡ Several elements are here enumerated as diatomic which are usually counted monatomic, and which are taken as such in the body of this work, on account of the inconvenience which would arise from the too great departure from established usage; partly also because the reasons for supposing some of them to be diatomic, though strong, cannot be considered quite conclusive. The question whether magnesium, zinc, cadmium, and mercury, and calcium, strontium, and barium, ought to be considered diatomic instead of monatomic, resolves itself into the question whether the accepted atomic weights of these elements ought to be doubled. We cannot discuss this question fully here, and must confine our-

2. *Triatomic Elements.*—Nitrogen ($N = 14$), phosphorus ($P = 31$), arsenic ($As = 75$), antimony ($Sb = 121$), bismuth ($Bi = 208$); boron ($B = 11$); gold ($Au = 197$); probably molybdenum ($Mo = 48$), vanadium ($Vd = 68 \cdot 5$), tungsten ($W = 92$); and perhaps others.

These elements do not form many combinations among themselves not containing any element belonging to another class. They combine with the monatomic elements in the proportion of 1 at. to 3, to form such bodies as NH^3, PH^3, AsH^3, $SbAg^3$, $BiCl^3$, BCl^3, $AuCl^3$, &c.; 1 at. of some of them can also combine with 5 monatomic atoms, many bodies of the following form being known: NH^4Cl, PH^4I, PCl^5, &c.; but none of these compounds appear to be capable of volatilising without decomposing, so as to regenerate a compound of the class first mentioned, as shown in the following examples:—

$$NH^4Cl = NH^3 + HCl$$
$$PCl^5 = PCl^3 + ClCl.$$

With the diatomic elements and with the diatomic and monatomic elements together, they combine in very various proportions, but always so that the sum of the triatomic atoms, or of the triatomic and monatomic atoms together, when the latter are present, contained in a molecule of the products formed, is an even number.

3. *Tetratomic Elements.*—Carbon ($C = 12$), silicon ($Si = 28 \cdot 5$), titanium ($Ti = 48 \cdot 5$), tin ($Sn = 118$), tantalum ($Ta = 138$); probably lead ($Pb = 207$), and perhaps other elements.

These elements can combine with the monatomic elements in the proportion of 1 at. to 2 (*e. g.* $SiCl^2$, $SnCl^2$), and with the diatomic elements in the proportion of 1 at. to 1 (*e. g.* CO, SiO, SnO); but the compounds so produced readily combine with 2 monatomic atoms, or with 1 diatomic atom, to form such bodies as the following: $SiCl^4$, $SnCl^4$, $COCl^2$, CO^2, SiO^2, &c., which appear to represent the normal compounds of the tetratomic elements. They also form very many compounds with the triatomic elements, or with these and the monatomic or diatomic elements together. The following are examples of the simplest combinations so produced:

$$C^2N^2,\ CNH,\ CNHO.$$

4. *Hexatomic Elements.*—The following elements are perhaps hexatomic: iron ($Fe = 112$), aluminium ($Al = 54$), and other similar bodies.

---

selves to the statement of certain facts whose bearing on the point will be understood if the reader has studied the article ATOMIC WEIGHTS.

α. *Magnesium, Zinc, Cadmium, Mercury.*—Of these four elements it may be said, that the evidence in favour of doubling the atomic weights of zinc and mercury is conclusive, while magnesium and cadmium are so obviously members of the same natural family, that it is not possible to double the atomic weights of the former two metals without doubling theirs also. The most important reason for doubling the atomic weights of zinc and mercury are the following:—When these metals act upon the iodides of the alcohol-radicles, 65 pts. zinc or 200 pts. mercury combine directly with the quantities represented by the formulæ CH^3I, C^2H^5I, $C^5H^{11}I$, C^3H^5I, in each case forming a single product, such as $Zn''C^2H^5I$, $Hg''C^2H^5I$, $Hg''C^3H^5I$, &c., as though 65 pts. zinc and 200 pts. mercury, represented indivisible quantities, or atoms, of those metals, whereas if these weights represented two atoms, we should expect that the action of 65 pts. zinc or of 200 pts. mercury on C^2H^5I would give rise to two distinct products, ethylide and iodide of zinc or of mercury. The combination which actually takes place is analogous to the combination of (the diatomic element) oxygen with cyanide of potassium:

$$KCy + O = KCyO\,;$$

if zinc and mercury were monatomic, their action on the hydriodic ethers would probably be analogous to that of (the monatomic element) chlorine on cyanide of potassium:

$$KCy + Cl^2 = KCl + CyCl.$$

Again, the reactions represented by the following equations (and the similar reactions which take place with mercury-methyl) all tend to show that a molecule of mercury-ethyl (or mercury-methyl) contains 2 at. ethyl (or methyl):

$$\overset{''}{Hg}(C^2H^5)(C^2H^5) + BrBr = \overset{''}{Hg}(C^2H^5)Br + C^2H^5.Br \text{ (Buckton).}$$
$$\overset{''}{Hg}(C^2H^5)(C^2H^5) + ClH = \overset{''}{Hg}(C^2H^5)Cl + C^2H^5.H \text{ (Buckton).}$$
$$\overset{''}{Hg}(C^2H^5)(C^2H^5) + \overset{''}{Hg}ClCl = \overset{''}{Hg}(C^2H^5)Cl + \overset{''}{Hg}Cl(C^2H^5) \text{ (Buckton),}$$

and it is difficult to understand what can cause the two atoms of alcohol-radicle to remain combined, if it be not that the quantity of mercury with which they are united is one indivisible atom.

To these chemical arguments may be added that drawn from the determinations which have been made of the vapour-densities of zinc and mercury compounds. All the determinations hitherto made agree with the supposition that the atomic weights of these metals are 65 and 200 respectively, and not 32·5 and 100, as generally admitted; the specific heats of these metals point also to the same conclusion.

We may add, finally, that the readiness with which all the four metals under consideration form basic salts is a further indication of their diatomic character.

β. *Calcium, Strontium, Barium.*—The decomposition of the hydrates of these metals by heat alone, taken in connection with their general close resemblance to the alkalis, may be regarded as evidence of their being hydrates of diatomic radicles bearing the same relation to the hydrates of potassium, sodium, &c., that the bibasic acids (most of which are similarly decomposed by heat) bear to the monobasic acids. Moreover, the non-existence of acid carbonates, sulphates, oxalates, &c., of any of them seems to show that the quantities of metal (twice the quantities usually admitted as representing their atomic weights) contained in their neutral salts with bibasic acids are indivisible. Notwithstanding, however, these and some other indications of a diatomic character, the atomicity of calcium, strontium, and barium must be considered as still more or less open to question.

The existence of this class is not as yet certainly proved; there is, however, reason to believe that iron, aluminium, and perhaps some of the metals most closely allied to them, are hexatomic, and that their simplest compounds with the monatomic elements contain 6 monatomic atoms (*e.g.* sesquichloride of iron, $FeCl^6$; chloride of aluminium, $AlCl^6$).

Notwithstanding the exceptions which we have pointed out, the difference in the modes of combination of various elements, which have been indicated as serving for their division into distinct classes, are in the main so marked and so constant as almost to make the conclusion unavoidable that they result from differences in the combining capacity of the elementary atoms themselves; that in fact the *atomic combining capacity* or *atomicity* of the various elements is a definite and fixed property comparable to their atomic weight. And, if it be accordingly admitted that an atom of oxygen, or of any other element of the same class, can combine with *twice* as great a weight of any given element as an atom of hydrogen, or of any other element of its class,—that an atom of any element of the nitrogen-class can combine with *three* times as much, and an atom of any element of the carbon-class with *four* times as much (that is, if the terms monatomic, diatomic, triatomic, and tetratomic, applied to the various classes into which the elementary bodies have been divided, be admitted to correspond to actual differences in the combining powers of the *atoms* of the elements),—then it is possible to explain, at least to a very great extent, the general differences of composition which the compounds of these elements show when compared together.

Upon the classification of the elementary bodies which we have here adopted, we have now to found a classification of their compounds. [In this part of the subject it will often be convenient to use the following general signs for denoting elements of the various classes:

For monatomic elements, a vertical or horizontal stroke: | or —

For diatomic elements, two such strokes connected at one end by a straight line  or 

For triatomic elements, three strokes connected:  or 

For tetratomic elements, four strokes connected:  or 

The number of strokes in the sign of each class of elements thus represents their atomicity.]

The simplest normal combinations which one monatomic, diatomic, triatomic, or tetratomic atom respectively can form, are the following:

1. Monatomic atom with monatomic, — —; example: $\overset{\prime}{H}\overset{\prime}{Cl}$.

2. *a.* Diatomic atom with 2 monatomic, ; examples: $\overset{\prime\prime}{O}\overset{\prime}{H}{}^2$, $\overset{\prime\prime}{O}\overset{\prime}{H}\overset{\prime}{K}$.

b. Diatomic atom with diatomic, ; example: $\overset{\prime\prime}{O}\overset{\prime\prime}{Hg}$.

3. *a.* Triatomic atom with 3 monatomic, ; example: $\overset{\prime\prime\prime}{N}\overset{\prime}{H}{}^3$, $\overset{\prime\prime\prime}{N}\overset{\prime}{H}{}^2\overset{\prime}{K}$.

b. Triatomic atom with 1 monatomic and 1 diatomic, ; examples: $\overset{\prime\prime\prime}{N}\overset{\prime}{Cl}\overset{\prime\prime}{O}$ $\overset{\prime\prime\prime}{Sb}\overset{\prime}{Cl}\overset{\prime\prime}{O}$.

c. Triatomic atom with triatomic, ; example: $\overset{\prime\prime\prime}{N}\overset{\prime\prime\prime}{B}$.

4. *a.* Tetratomic atom with 4 monatomic, ; examples: $\overset{iv}{C}\overset{\prime}{H}{}^4$, $\overset{iv}{C}\overset{\prime}{H}\overset{\prime}{Cl}{}^3$, $\overset{iv}{C}\overset{\prime}{H}{}^2\overset{\prime}{I}{}^2$.

b. Tetratomic atom with 2 diatomic, ; examples: $\overset{iv}{C}\overset{\prime\prime}{S}{}^2$, $\overset{iv}{Si}\overset{\prime\prime}{O}{}^2$.

c. Tetratomic atom with 2 monatomic and 1 diatomic, ; examples: $\overset{iv}{C}\overset{\prime}{Cl}{}^2\overset{\prime\prime}{O}$, $\overset{iv}{Pb}\overset{\prime}{Cl}{}^2\overset{\prime\prime}{O}$.

d. Tetratomic atom with 1 monatomic and 1 triatomic, ; example: $\overset{iv}{C}H\overset{'''}{N}$.

e. Tetratomic atom with tetratomic, 
It will be seen that this classification of compounds of the simplest order is equivalent to Gerhardt's classification according to types. Compounds of the form 1 are those referred by him to the type HCl or HH; those of the form 2*a*, are those referred to the type H^2O; those of the form 3*a*, are those referred to the type H^3N; while bodies of the form 4*a* may be referred to the type H^4C, subsequently introduced (by Odling, Kekulé, and others) for the purpose of further extending Gerhardt's system. The sub-forms 2*b*, 3*b*, 3*c*, 4*b*, 4*c*, 4*d*, 4*e*, may be regarded as deriving from the primary forms, if we take account of the multequivalency of the polyatomic elements (see EQUIVALENTS), and consider, for instance, chloroxide of carbon (4*c*) as representing a body of the form 4*a*, in which the diequivalent atom O takes the place of 2 monatomic atoms, and hydrocyanic acid (4*d*) as a body of the same form in which the triequivalent atom N takes the place of 3 monatomic atoms. In this way all bodies such as those above mentioned, may be referred to the four types HCl, H^2O, H^3N, H^4C; so far, then, the empirical classification of Gerhardt, and that which we have here deduced from the theoretical basis of the definite atomicity of the elements, are identical.

In order to extend his classification to compounds of a higher degree of complexity, Gerhardt was obliged to assume the existence of an indefinite number of compound radicles: we have now to consider the constitution of such compounds, and shall thus see that the idea of the atomicity of the elements includes, not only the idea of types, but also the idea of compound radicles,—ideas which recent chemistry has shown to be correlative, neither of them having any significance except in relation to the other.

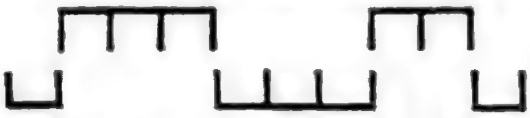
Comparing now more complex compounds with each other and with the very simple compounds of which we have been speaking, we find that, whereas there is no rule as to the number of diatomic or tetratomic atoms which one compound may contain more or less than are contained in another, the difference between the number of monatomic or of triatomic atoms, or of monatomic and triatomic atoms together when both are present, contained in two well defined and well analysed bodies, is always an even number. But since the compounds constituted according to any of the forms above enumerated always contain an even number of monatomic, or of triatomic, or of monatomic and triatomic atoms together, this amounts to saying that *the sum of such atoms contained in any well-defined and well-analysed body is always an even number.* This proposition embodies one of the earliest observed regularities in the atomic composition of compound bodies (*vid.* Laurent, Ann. Ch. Phys. [3] xviii. 266), often spoken of as *the law of the even number of atoms*, and is in strict accordance with the view which regards the combination of the elements as consisting in the mutual saturation of their atomic combining capacities, and might indeed be deduced from it; for since each unit of combining capacity requires another for its saturation, the number of atoms in every normal compound (or compound in which the atomicity of each element is saturated) must be such that the number representing the sum of their combining capacities is even; and this can only be the case when it contains an even number of those atoms (monatomic and triatomic atoms) whose atomicity is represented by an odd number.

The highest number of monatomic atoms that any compound can contain appears to be regulated by the number and nature of the polyatomic atoms which it contains. If a compound contain n polyatomic atoms whose atomicities are respectively A, A′, A″, &c., the highest number of monatomic atoms that it can contain is $A + A' + A'' + \ldots . - 2(n-1)$; but it may contain any lower number differing from this by a multiple of 2.

We may illustrate this rule by applying it to the simplest normal compounds of atoms of each degree of atomicity. In the case of compounds of the form 1 (– –), A + A′, &c., = 0, n also = 0, therefore the formula becomes $-2(-1) = 2$; in the case of compounds of the form 2*a*, (), A′, A″, &c., disappear, and $n = 1$, so that the term $2(n-1)$ also disappears, and the formula is reduced to $A = 2$, in like manner in the case of compounds of the form 3*a*, (), the formula becomes $A = 3$; and in the case of those of the form 4*a*, (), it becomes $A = 4$. All compounds belonging to any of these four classes, contain therefore the maximum number of monatomic atoms. We have previously alluded to some substances in which this maximum appears to be exceeded: namely, first, compounds containing *four* or *six* monatomic atoms, such as $NaAgCl^2$ (?) and K^2AgI^3; secondly, compounds containing *five* monatomic atoms to one triatomic atom, such as NH^4Cl, PCl^5, &c. There is, however, as already pointed out, reason to believe that all such bodies as these are not strictly speaking chemical individuals, but that they are combinations of entire molecules, as such, held together by a force analogous to that which causes certain salts to combine with water of crystallisation. This view may be easily admitted with reference to the first set of exceptional substances, because they cannot be proved to exist, except in the crystalline state: being generally decomposed by solution in a moderate quantity of water, they are often not very constant in the proportions of their ingredients, and the two salts, of which they may be regarded as made up, retain their usual properties without essential alteration. In the case of some of the second class of exceptional bodies, the difficulties in the way of admitting this explanation are greater. These bodies are so numerous, and some of them form so readily and are under certain ordinary conditions so stable, that some chemists have been led to regard nitrogen, phosphorus, arsenic and antimony as pentatomic instead of triatomic. The chief reason for not adopting this conclusion is that, in all such compounds, two of the monatomic atoms appear to be more loosely combined than the other three, so that even the most stable compounds of this kind, namely the ammonia-salts, are always decomposed to a greater or less extent by the evaporation of their solutions, and not one body of this class appears to be volatile without decomposition (into a compound of the form 1, and a compound of the form 3*a*). But whatever be the real nature of these compounds and of the force which causes their formation, it is certain that they differ in important respects from substances whose composition accords with the atomicity of their components, and that their properties are to a great extent explicable if we regard them as combinations of entire molecules produced independently of the combining capacities of their constituent atoms. (To prevent repetition, we may state here that the same view is applicable to all other compounds of ammonia and similar bodies with acids.)

But to return and consider how far the composition of other bodies agrees with the formula which we have said gives the highest possible number of monatomic atoms that they can contain. It results from the formula that bodies containing two diatomic atoms can contain also two monatomic atoms. Accordingly there exist not only compounds of the form  (referred to above by the number 2*b*), but also compounds of the form , for example, $SOCl^2$, O^2H^2. For bodies containing one triatomic and one diatomic atom, the formula gives 3 as the highest number of monatomic atoms that they can contain; accordingly, in addition to compounds of the form 3*b*, there exist compounds of the form , for example, $NOCl^3$, $POCl^3$. Bodies like those of the form 3*c*, containing two triatomic atoms may, according to the formula, contain at most four monatomic atoms: agreeably with this result, compounds are known of the form , for example, $NPCl^2$, and of the form , for example, P^2I^4. Bodies containing one tetratomic and two diatomic atoms (4*b*) may by the same rule contain *four* monatomic atoms: hence we may have bodies of the form  example, CO^2H^2 (formic acid), and bodies of the form ; methylic glycol, CO^2H^4, if known, would be an example of this class. Similarly, bodies containing one tetratomic and one diatomic atom (4*c*) may contain four monatomic atoms, forming compounds of the form , for example, COH^4 (methylic alcohol), CSH^4 (methylic mercaptan); bodies containing one tetratomic and one triatomic atom (4*d*) may contain five monatomic atoms, forming compounds of the form 
for example, CNH^5 (methylamine); and bodies containing two tetratomic atoms (4*e*), may contain two, four, or six monatomic atoms giving compounds of the form , example, C^2H^2 (acetylene); , example, C^2H^4 (ethylene); or  example, C^2H^6 (hydride of ethyl)

The question now arises, how far is this law of the combination of the different elements in accordance with the idea of their having each a definite and constant atomicity? A little consideration will show that it is a necessary consequence of that supposition. The total combining capacity of any number of atoms is evidently the sum of their several combining capacities, and if these latter be denoted by A, A', A'', &c., will be expressed by $A + A' + A'' + \ldots.$; but if the atoms be combined together, their total combining capacity will not be so great as in the free state, it will have been more or less saturated by the combination which has taken place among them. The atomicity of as many of them as are monatomic, will have been entirely saturated by the combination, but the atomicity of such as are polyatomic may be only partially saturated; and it will be saturated to the smallest possible extent if, of all but two of them, two units of combining capacity be saturated each by one unit of a different atom, and if one unit of each of the remaining two atoms be saturated. This mode of combination is shown by the following diagram, representing 2 tetratomic atoms, 1 triatomic atom, and 2 diatomic atoms combined in the way described: —



Since the free atomicity (if we may use the expression) of all but two atoms is thus diminished by two units, and the free atomicity of each of the remaining two atoms is diminished by one unit, the total remaining free atomicity of the group is equal to the total atomicity of the uncombined atoms (or $A + A' + A'' + \ldots.$), diminished by $(2(n-2) + 2)$,

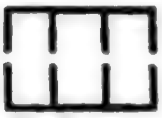
$$\text{that is:}\quad A + A' + A'' + \ldots. -2(n-2) - 2 = A + A' + A'' + \ldots. -2(n-1),$$

which is the precise expression, some of whose consequences we have above discussed.

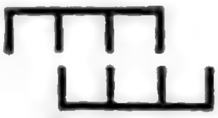
It is evident that no combination can take place without the saturation of at least two units of atomicity, one belonging to each of the combining atoms. Hence, when a monatomic atom combines with any other atom, or group of atoms, the atomicity of the product must be one less than that of such atom or group of atoms: for the monatomic atom brings to the compound that is formed only one unit of atomicity, whereas two units are saturated by the combination. Therefore, as we have seen, the number of monatomic atoms with which any atom or group of atoms can combine, is always limited. For similar reasons the total atomicity of any atom or group is the same as that of its compound with a diatomic atom. From this follow the several consequences: first, there is *a priori* no assignable limit to the number of diatomic atoms with which a given atom or group may combine; secondly, compounds which do not contain atoms whose atomicity is represented by a higher number than 2, never contain more than two monatomic atoms; *e.g.* water, H^2O, and sulphydric acid, H^2S, each contain two monatomic and one diatomic atom, while pentathionic acid, $H^2S^5O^6$, contains eleven diatomic, but still only two monatomic atoms; thirdly, compounds containing the maximum number of monatomic atoms do not become able to combine with a greater number through union with any number of diatomic atoms; *e.g.* hydride of hexylene, C^6H^{14}, contains the maximum of monatomic atoms, but mannite, $C^6H^{14}O^6$, differing from it by containing O^6 additional, is not capable of further combination with monatomic atoms. When a triatomic atom enters into combination, it brings to the compound three units of atomicity, and two units are saturated by the combination, so that the entire atomicity of the product exceeds that of the original substance by one. Hence, when a triatomic element, as nitrogen, combines with a group already containing the maximum of monatomic atoms, the group becomes able to take up an additional monatomic atom; accordingly, we have many compounds which differ by NH, or a multiple of it, *e.g.*, C^2H^6 (hydride of ethyl), C^2H^7N (ethylamine), $C^2H^8N^2$ (ethylene-diamine); C^2H^4O (aldehyde), C^2H^5NO (acetamide); $C^2H^4O^2$ (acetic acid), $C^2H^5NO^2$ (glycocine). When a tetratomic atom is added to a group, the total atomicity of the product in like manner exceeds that of the original substance by 2. Hence the possibility of the many series of compounds of which the terms differ by CH^2 or by a multiple thereof.

It will be understood that the foregoing remarks touching the combining capacity of various atomic groupings, and the way in which it is affected by the addition of atoms of various kinds, have reference only to the *highest number* of monatomic atoms that is ever found in combination with a given number of polyatomic atoms; and that it is by no means intended to imply that all compounds contain, or even show any great tendency to combine with, the whole number of monatomic atoms which the rules above given indicate as the maximum in each case. Several compounds not containing the maximum of monatomic atoms have already been incidentally referred to; but it is necessary that the constitution of such compounds should be somewhat more specially discussed in relation to the theory of the definite combining capacity of the elementary atoms.

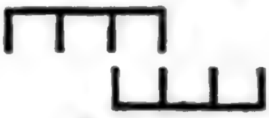
According to this theory, there are four different ways in which it is possible for two tetratomic atoms, for instance, two atoms of carbon, to combine. Two such atoms may mutually saturate, either the whole, three fourths, one half, or one fourth of each other's combining capacity, as expressed by the following diagrams: —



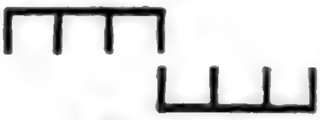
Each atom completely saturated.



Each atom ¾ saturated.



Each atom ½ saturated.



Each atom ¼ saturated.

The first diagram probably represents some variety of free carbon; the second, third, and fourth, the manner in which the two carbon-atoms are combined in acetylene, C^2H^2, ethylene, C^2H^4, and hydride of ethyl, C^2H^6, respectively. In the last of these bodies, one unit only of the combining capacity of each carbon-atom is saturated by the other, leaving three units of affinity belonging to each free for combination with hydrogen; and it is plain that two atoms of carbon can only combine with a larger number of hydrogen, or other monatomic atoms, than are contained in this compound, when they are entirely uncombined with each other. In ethylene and acetylene, on the other hand, the two atoms of carbon are so combined that, if we may so speak, they can combine with an additional number of monatomic atoms by loosening, without entirely giving up, their hold upon each other. And in all compounds in which the proportion of monatomic to polyatomic atoms is below the maximum indicated by the formula given higher up, we must, unless we suppose the atomicity of the elements to be variable (in which case the word atomicity ceases to have any special meaning), suppose that a greater or lesser number of the polyatomic atoms are combined in a similar way. But, in the great majority of such cases, the composition alone of a compound does not enable us to decide as to how many of its polyatomic atoms are in this kind of more intimate union with each other. For example, allylene, C^3H^4, homologous with acetylene, might, so far as its mere composition is concerned, be constituted either thus , or thus ; its properties, however, would be somewhat different in the two cases. It would not be possible to combine a compound constituted in the first manner with two atoms of hydrogen, without transforming it into propylene, C^3H^6, or an isomeric body; but it would doubtless be possible, under appropriate conditions, to cause a body constituted in the second manner to split up, by the addition of two atoms of hydrogen, into marsh-gas, CH^4 or , and acetylene, C^2H^2, or .

In the preceding part of this article, we have tried to show that those of the elements which have been sufficiently studied may be divided into distinct classes, according to the manner in which they enter into combination, and further, that each element possesses a certain definite atomic combining capacity, which regulates the formation of its most complex as well as of its simplest compounds. By the application of this principle of the definite atomicity of the elements, it would be easy to construct tables showing all the possible combinations of each element; all compounds whose constitution was sufficiently understood, might then be classified by inserting them in their places in these tables. But since the place of any compound would be determined, not only by its composition, but also by the mode or order of combination of its atoms, a point concerning which we have, in most cases, no definite knowledge, such a system of classification would not be widely applicable in the present state of chemistry. Our acquaintance with the great majority of the more complex compounds consists in the knowledge of transformations, by which only a small number of their atoms are affected. It has, therefore, been found convenient, for the purposes of classification to regard such compounds as consisting of two parts, namely, the atom or atoms which take part in their known transformations, and a residue, or nucleus, or radicle, which is unaffected by these transformations, and appears as a constant constituent in all the products to which they give rise. By aid of this convention, the classification founded upon the atomicity of their elements, which, as we have seen, is applicable to the more simple compounds, may be extended so as to comprehend all tolerably well known substances. The radicles, whose existence this view supposes, may be of any degree of complexity; their nature and their relation to the compounds in which they are contained will be most easily understood by considering a few of the simplest of them.

Hydrochloric acid, HCl, water, H^2O, ammonia, H^3N, and marsh-gas, H^4C, have already been shown to be compounds, each of which may be taken as the representative of a whole class of bodies. If we imagine 1 atom of hydrogen to be removed from each of these substances, it is plain that the residues Cl, HO, H^2N, H^3C, will each be able to combine with an atom of hydrogen to reproduce the original compounds, or with some other monatomic atom, such as chlorine or potassium, to form such bodies as:

$$KCl,\ ClCl;\quad KHO,\ ClHO;\quad KH^2N;\quad KH^3C,\ ClH^3C;\ \&c.$$

It is plain also, since 1 at. of a diatomic element is equivalent in combining capacity to 2 monatomic atoms, that 1 at. of oxygen, sulphur, &c., will combine with 2 at. of each of these residues, or with two different residues at once, or with 1 at. of a residue and with 1 at. of a monatomic element, forming such compounds as the following:

$$O\left\{\begin{matrix}Cl\\Cl\end{matrix}\right.,\quad O\left\{\begin{matrix}H^3C\\H^3C\end{matrix}\right.,\quad O\left\{\begin{matrix}H^3C\\H^5C^{2}*\end{matrix}\right.,\quad O\left\{\begin{matrix}H^3C\\H\end{matrix}\right.,\quad O\left\{\begin{matrix}H^3C\\K\end{matrix}\right.,\ \&c.$$

For similar reasons, it is evident that 1 at. of a triatomic element will combine with 3 at. of such residues, or with 2 at. of residue and 1 at. of a monatomic element, or with 1 at. of residue and 2 monatomic elementary atoms, *e. g.*:

$$N\left\{\begin{matrix}Cl\\Cl\\Cl\end{matrix}\right.,\quad N\left\{\begin{matrix}H^3C\\H^3C\\H^3C\end{matrix}\right.,\quad N\left\{\begin{matrix}H^3C\\H^5C^2\\H^{11}C^5\dagger\end{matrix}\right.,\quad N\left\{\begin{matrix}H^3C\\H^3C\\H\end{matrix}\right.,\quad N\left\{\begin{matrix}H^3C\\H\\H\end{matrix}\right.,\ \&c.$$

In like manner, 1 at. of a tetratomic element will combine with 4 at. of residue, or with 4 at. partly of residue and partly elementary, *e. g.*:

$$C\left\{\begin{matrix}Cl\\Cl\\Cl\\Cl\end{matrix}\right.,\quad C\left\{\begin{matrix}H^3C\\H\\H\\H\end{matrix}\right.,\quad C\left\{\begin{matrix}HO\\H\\H\\H\end{matrix}\right.,\quad C\left\{\begin{matrix}HO\\H^3C\\H\\H\end{matrix}\right.,\ \&c.$$

From all this it follows that these residues or radicles follow the same laws of combination with the elementary bodies of different classes as do the monatomic elements themselves. Further, they combine also with one another according to the same laws as are followed by elementary monatomic atoms; that is, they combine together in the proportion of 1 at. to 1 at., *e. g.*:

$$Cl + H^3C = ClH^3C$$

Chloride of methyl.

$$HO + H^3C = OH^3C$$

Methylic alcohol.

$$H^2N + H^3C = NH^5C$$

Methylamine.

$$H^3C + H^3C = H^6C^2$$

Free methyl.

But, just as there are not only monatomic but also polyatomic elements, so there are polyatomic as well as monatomic radicles. If we suppose H^2 to be withdrawn from each of the compounds H^2O, H^3N, H^4C, it is evident that the residues O, HN, H^2C, will have the properties of diatomic radicles, the compound radicles HN and H^2C being similar in their combining capacity to the simple radicle O, just as the compound radicles HO, H^2N, and H^3C, resemble the simple radicle Cl in their combining capacity. After the detailed illustration of the properties of the monatomic radicles given above, it is not necessary to dwell upon the characters of the diatomic radicles, since what has been said of the former applies, *mutatis mutandis*, to the latter.

In like manner, the abstraction of H^3 from H^3N and H^4C gives the triatomic radicles N and HC; and the withdrawal of H^4 from any normal compound leaves a tetratomic radicle analogous in properties to the simple radicle C, which results from the withdrawal of H^4 from H^4C.

---

* $H^5C^2 = H^6C^2 - H$: it is a residue or radicle comparable to H^3C.

† $H^{11}C^5 = H^{12}C^5 - H$.

Although, in considering the properties and combinations of these or of other compound radicles, we may confine our view to their analogies with the elementary bodies and regard their atomicity as an ultimate property, which, like the atomicity of the elements, is not to be explained, it is easy to see that the atomicity of the radicles of which we have spoken, is the direct result of their composition and the atomicity of their component atoms. It only requires to be put into words to be at once evident that, if one, two, three, or more monatomic atoms be removed from any normal compound whatever, the remainder will be a substance possessing one, two, three, or more units of atomicity free for combining with other bodies, and therefore, as to its power of combination, exactly analogous to an atom of an element whose atomicity is represented by one, two, three, or a higher number. Hence the derivation of any compound radicle determines its atomicity. The maximum atomicity of a radicle may also be always deduced from its composition by means of the formula $A + A' + A'' + \ldots - 2(n-1)$, in which A, A', A'', &c., indicate the atomicities of the elementary atoms, monatomic as well as polyatomic, of which the radicle is composed, and *n* the number of atoms it contains. From this formula it follows that a compound radicle can never consist of monatomic atoms only; that radicles containing only diatomic atoms are always diatomic; and that the atomicity of radicles containing only tetratomic, or tetratomic and diatomic atoms, is always represented by 2, 4, or some other even number. It follows also from the same formula, and from what has been previously said as to the composition of complex compounds in general, that, starting from the simple radicles already described, there may exist series of radicles of the same atomicity in which the common difference is , *e. g.* O; or , *e.g.* HN; or , *e.g.* CH^2.

For example:

Common difference, 		*Common difference,* 		*Common difference,* 		
Cl	O	HO	H	CH^3	CH^2	CH
ClO	SO	PH^2O (in hypophosphites)	NH^2	C^2H^5	C^2H^4	C^2H^3
ClO^2	SO^2			C^3H^7	C^3H^6	C^3H^5
ClO^3				&c.	&c.	&c.
ClO^4						

From these, considered as primary radicles, so-called *derived* or *conjugate* radicles may arise by equivalent substitution; for instance, by substitution of Cl, Br, or I, for H; of O or S for H^2; of S for O; of N for H^3, or for HO^3, &c.; or of NO^2 or NH^2 for H; or of SO^2 or CO for H^2, or generally of any radicle for its equivalent. Again, still other radicles exist differing from these by containing some multiple of H^2 (or its equivalent) less than they do, but possessing the same atomicity; for example, we have ethyl, C^2H^5, and vinyl, C^2H^3; trityl, C^3H^7, and allyl, C^3H^5; propionyl, C^3H^5O, and acryl, C^3H^3O; hexyl, C^6H^{13}, and phenyl, C^6H^5; all of them monatomic radicles.

Hence it follows that triatomic radicles may often be isomeric with monatomic radicles; for example, *acetyl* (Berzelius) C^2H^3, triatomic, with *vinyl*, C^2H^3, monatomic; *glyceryl*, C^3H^5, triatomic, with *allyl*, C^3H^5, monatomic; in like manner, tetratomic and diatomic radicles may be isomeric with each other; for example, *tartryl*, $C^4H^2O^2$, tetratomic (tartaric acid = $\left.\begin{matrix}(C^4H^2O^2)^{iv}\\ H^4\end{matrix}\right\}O^4$), with *fumaryl*, $C^4H^2O^2$, diatomic (fumaric acid = $\left.\begin{matrix}(C^4H^2O^2)''\\ H^2\end{matrix}\right\}O^2$). In such cases, we must suppose that the carbon (or other polyatomic atoms) of the radicles which contain a smaller proportion of hydrogen, or which have a lower atomicity, are more intimately combined with each other than they are in those which, having the same atomicity, contain a larger proportion of hydrogen, or with the same composition have a higher atomicity.

We have hitherto spoken only of the composition and atomicity of compound radicles; it remains to explain a little more fully the grounds upon which their existence in various compounds is assumed, and what that assumption is intended to imply. It has been said that compound radicles are groups of elements which are contained in a greater or lesser number of bodies, and are unaltered in the reactions by which one of these is transformed into another. For instance, the bodies of the following series:—

C^7H^6O	Oil of bitter-almonds,
C^7H^5ClO	Chloride of benzoyl,
$C^7H^6O^2$	Benzoic acid,
C^7H^7ON	Benzamide,
C^8H^5ON	Cyanide of benzoyl,

contain the group C^7H^5O (benzoyl) as a common constituent which remains unchanged when they are transformed one into another. Now the reactions by which these transformations are effected are essentially quite similar to those by which the following bodies are changed one into another.—

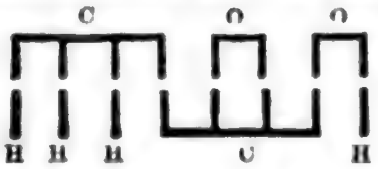
KH (?)	Hydride of potassium.
KCl	Chloride of potassium.
KHO	Hydrate of potassium.
KH^2N	Potassamine.
KCN	Cyanide of potassium.

This analogy is hidden if the formulæ of the bodies of the former series are written as above; but if they are written as containing the compound radicle benzoyl, C^7H^5O, the analogy becomes at once apparent:

$(C^7H^5O)H$	Hydride of benzoyl, or oil of bitter-almonds.
$(C^7H^5O)Cl$	Chloride of benzoyl.
$(C^7H^5O)HO$	Hydrate of benzoyl, or benzoic acid.
$(C^7H^5O)H^2N$	Benzamide.
$(C^7H^5O)CN$	Cyanide of benzoyl.

These latter formulæ express that the bodies represented by them are functionally analogous to compounds of the monatomic elements, and that they respectively possess the general properties of those classes of bodies of which HCl, H^2O, H^3N, &c., are the typical representatives.

The precise nature of the radicle which any substance is represented as containing will naturally vary according as it is desired to express the relations of the substance in question to this or that series of other bodies, or its capability of undergoing this or that series of transformations. If, for example, we wish to express the relation in which acetic acid stands to aldehyde, chloride of acetyl, acetamide, &c., we shall do so most simply by representing it as the hydrate of the compound radicle acetyl, C^2H^3O, thus, $\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O$. But if it be desired to express also that, by distillation with excess of alkali, by electrolysis, or by distillation with arsenious acid, acetic acid is resolved into a compound of the methyl series and a compound of the carbonic series, and that it can be formed from sodium-methyl and carbonic anhydride, or from cyanide of methyl by the action of alkali, this must be expressed by representing the radicle C^2H^3O as composed of the simpler radicles CH^3 and CO; and if we further wish to express the analogy of acetic acid to formic acid, we must write acetyl thus, $C(CH^3)O$, or as formyl, CHO, in which hydrogen is replaced by methyl: the whole formula of acetic acid then becomes $\left.\begin{matrix}C(CH^3)O\\H\end{matrix}\right\}O$. Similarly, in order to express the relations of acetic acid to still other sets of compounds, we are obliged to represent it as containing radicles of continually simpler composition, until finally we come to represent it as built up from elementary atoms; for instance, thus:



Hence the idea of a compound radicle is seen to be entirely relative, the same body from one point of view appearing to contain one compound radicle, and from another point of view appearing to contain a different one. A comparison of the definition of an elementary body, given near the begining of this article, with that of a componud radicle, shows that compound radicles bear the same relation to certain more or less limited sets of chemical processes that the elements bear to all the chemical processes known.

The application of the principles which we have been discussing, to the classification of chemical compounds generally, is illustrated by the following table, which is a modification and extension of that given by Gerhardt (*Traité*, iv. 612, 613), and reproduced in *Graham's Elements of Chemistry* (2nd edit. ii. 528, 529). By referring to the detailed commentaries by which Gerhardt's table of classification is followed in the places referred to, the reader will be able to understand fully the meaning of this table without requiring further explanation in this place.

Classification

Compounds comparable to **Hydrochloric Acid,** HCl.				*Compounds comparable*	
Containing monatomic radicles (Chlorides, Hydrides, &c.)	Containing diatomic radicles (Dichlorides, Dihydrides, &c.)	Containing triatomic radicles (Trichlorides, Trihydrides, &c.)	Containing tetratomic radicles Tetrachlorides, Tetrahydrides, &c.)	Containing monatomic radicles (Oxides, &c.)	Containing diatomic radicles (Dioxides, &c.)
Basic chlorides, hydrides, cyanides, &c.				**Basic oxides, sulphides,**	
Haloïd salts.					
(chloride of potassium, KCl).	(chloride of mercury, $HgCl^2$).	(chloride of antimony, $SbCl^3$).	(chloride of tin, $SnCl^4$).	1. *Primary*, or *hydrates* (hydrate of potassium, KHO).	1. *Primary* (hydrate of calcium, CaH^2O^2).
Metallic hydrides (hydride of copper, *&c.*)				2. *Secondary*, or *anhydrides* (oxide of potassium, K^2O).	2. *Secondary* (soda-lime, Na^2CaO^2).
Metals proper and alloys.					
(potassium, KK.)	(silver-amalgam.)				
Alcoholic chlorides, hydrides, &c.				**Alcoholic oxides,**	
Halogen ethers.					
(chloride of ethyl, C^2H^5Cl).	(chloride of ethylene, $C^2H^4Cl^2$).	(trichlorhydrine, $C^3H^5Cl^3$)		1. *Primary* (common alcohol, $(C^2H^5)HO$).	1. *Primary* (glycol, $(C^2H^4)H^2O^2$).
Metallic compounds of alcohol-radicles.					
(potassium-ethyl, KC^2H^5).	(zinc-ethyl, $Zn(C^2H^5)^2$).	(bismethyl, $Bi(C^2H^5)^3$).	(plumbethyl, $Pb(C^2H^5)^4$).	2. *Secondary* (common ether, $(C^2H^5)^2O$).	2. *Secondary*.
				Intermediate oxides,	
				Monatomic oxysalts and ethers (chlorate of potassium, $(ClO^2)KO$; acetate of ethyl, $(C^2H^3O)(C^2H^5)O$).	Diatomic oxysalts and ethers (sulphate of potassium, $(SO^2)K^2O^2$; sulphate of ethyl, $(SO^2)(C^2H^5)^2O^2$)
Acid chlorides, hydrides, &c.				**Acid oxides,**	
Aci-chlorides.					
(chloride of acetyl, $(C^2H^3O)Cl$).	(chloride of succinyl, $(C^4H^4O^2)Cl^2$).	(chloride of phosphoryl, $(PO)Cl^3$).		1. *Primary* (acetic acid, $(C^2H^3O)HO$).	1. *Primary* (sulphuric acid, $(SO^2)H^2O^2$).
Aldehydes, acetones, &c.					
(acetic aldehyde, $(C^2H^3O)H$; acetone, $(C^2H^3O)(CH^3)$).				2. *Secondary* (acetic anhydride, $(C^2H^3O)^2O$).	2. *Secondary* (succinate of ethylene, $(C^4H^4O^2)(C^2H^4)O^2$).

ccording to *Types.*

Water, H^2O.		*Compounds comparable to* **Ammonia,** H^3N.			
Containing triatomic radicles (Trioxides, &c.)	Containing tetratomic radicles (Tetroxides, &c.)	Containing monatomic radicles (Amines and Amides).	Containing diatomic radicles (Diamines and Diamides).	Containing triatomic radicles (Triamines and Triamides).	Containing tetratomic radicles (Tetramines and Tetramides).
elenides, &c.		**Basic nitrides, phosphides, arsenides, &c.**			
. *Primary* (hydrate of bismuth, BiH^3O^3).	1. *Primary.*	1. *Primary* (amide of potassium, KH^2N).	1. *Primary* (zincamide, $\overset{\prime\prime}{Zn}H^4N^2$).	1. *Primary.*	1. *Primary.*
Secondary (oxide of bismuth, Bi^2O^3).	2. *Secondary.*	2. *Secondary.*	2. *Secondary.*	2. *Secondary.*	2. *Secondary.*
		3. *Tertiary* (nitride of potassium, K^3N).	3. *Tertiary* (nitride of zinc, Zn^3N^2).	3. *Tertiary.*	3. *Tertiary.*
ulphides, &c.		**Alcoholic nitrides, phosphides, &c.**			
. *Primary* (glycerin, $(C^3H^5)H^3O^3$).	1. *Primary.*	1. *Primary* (ethylamine, $(C^2H^5)H^2N$).	1. *Primary* (ethylenediamine, $(C^2H^4)H^4N^2$).	1. *Primary.*	1. *Primary.*
Secondary (oxide of glyceryl, $(C^3H^5)^2O^3$).	2. *Secondary.*	2. *Secondary* (diethylamine, $(C^2H^5)^2HN$).	2. *Secondary* (diethylenediamine, $(C^2H^4)^2H^2N^2$).	2. *Secondary.*	2. *Secondary.*
		3. *Tertiary* (triethylamine, $(C^2H^5)^3N$).	3. *Tertiary* (triethylenediamine, $(C^2H^4)^3N^2$).	3. *Tertiary.*	3. *Tertiary.*
ulphides, &c.		**Intermediate nitrides, phosphides, &c.**			
riatomic oxysalts and ethers (phosphate of bismuth, $(PO)BiO^3$; phosphate of ethyl, $PO)(C^2H^5)^3O^3$).	Tetratomic oxysalts and ethers (orthosilicates, orthosilicate of ethyl, $Si(C^2H^5)^4O^4$).	Monalkalamides (ethyl-acetamide, $(C^2H^5)(C^2H^3O)HN$; silver-acetamide, $Ag(C^2H^3O)HN$).	Dialkalamides, (oxanilide, $(C^2O^2)(C^6H^5)^2N^2$).	Trialkalamides (citranilide, $(C^6H^5O^4)(C^6H^5)^3H^3N^3$)	Tetralkalamides.
ulphides, &c.		**Acid nitrides, phosphides, &c.**			
Primary (phosphoric acid, $(PO)H^3O^3$).	1. *Primary* (tartaric acid, $(C^4H^2O^2)H^4O^4$).	1. *Primary* (acetamide, $(C^2H^3O)H^2N$).	1. *Primary* (oxamide, $(C^2O^2)H^4N^2$).	1. *Primary* (phosphotriamide, $(PO)H^6N^3$).	1. *Primary.*
Secondary (phosphoric anhydride, $(PO)^2O^5$).	2. *Secondary.*	2. *Secondary* (diacetamide, $(C^2H^3O)^2HN$).	2. *Secondary.*	2. *Secondary.*	2. *Secondary.*
		3. *Tertiary* (dibenzoyl-sulpho-phenylamide, $(C^7H^5O)^2(C^6H^5SO^2)N$).	3. *Tertiary.* (trisuccinamide, $(C^4H^4O^2)^3N^2$).	3. *Tertiary.*	3. *Tertiary.*

The groups into which chemical substances are here divided, may be considered as representing the principal varieties, but they are far from including all chemical compounds. By means of polyatomic radicles, molecules may be built up of much greater complexity than any shown in this table. There appears to be no assignable limit to the number of such compounds or to the degree of complexity which they may reach. Without discussing these bodies at length, we shall be able, by a few examples, to illustrate their nature and their relation to more simple substances. One of the most remarkable series of bodies of the kind to which we refer, are the polyethylenic alcohols of Lourenço and Wurtz. These chemists have shown that glycol, $(C^2H^4)H^2O^2$, is able to fix upon itself the elements of several molecules of oxide of ethylene, so as to give the following series of products:

$(C^2H^4)^2H^2O^3$	$(C^2H^4)^3H^2O^4$	$(C^2H^4)^4H^2O^5$	$(C^2H^4)^5H^2O^6$	$(C^2H^4)^6H^2O^7$
Diethylenic alcohol.	Triethylenic alcohol.	Tetrethylenic alcohol.	Pentethylenic alcohol.	Hexethylenic alcohol.

The principal transformations of glycol (monethylenic alcohol) itself are most conveniently expressed by representing it as containing the diatomic radicle ethylene, C^2H^4. With this radicle we must suppose the 2 at. of oxygen contained in glycol to be combined in such a manner that half the combining capacity of each is saturated by half the combining capacity of the radicle, the other half of the combining capacity of each atom of oxygen being saturated by an atom of hydrogen. This view of the constitution of glycol is expressed by the following formula, $\begin{array}{ll} \mathrm{H} & \\ & \}\mathrm{O} \\ (C^2H^4)'' & \\ & \}\mathrm{O} \\ \mathrm{H} & \end{array}$. Thus regarded, glycol may be compared to water by representing it as two molecules of water in which H^2 is replaced by $(C^2H^4)''$. The polyethylenic alcohols then become comparable to glycol if viewed as 3, 4, 5, &c., molecules of water in which respectively $(C^2H^4)^2$, $(C^2H^4)^3$, $(C^2H^4)^4$, &c., replaces an equivalent quantity of hydrogen. This comparison is expressed by the formulæ by which these compounds are represented above; but their relation to glycol becomes perhaps still more apparent if the same formulæ be written a little differently, so as to be directly comparable with that last given for glycol. Below are the formulæ of some of them so written, side by side with sulphur-compounds, which may be regarded as of analogous constitution.

$$\begin{array}{ll} \mathrm{H} & \\ & \}\mathrm{O} \\ (C^2H^4)'' & \\ & \}\mathrm{O} \\ \mathrm{H} & \end{array}$$

Glycol.

$$\begin{array}{ll} \mathrm{Cl} & \\ & \}\mathrm{O} \\ (S)'' & \\ & \}\mathrm{O} \\ \mathrm{Cl} & \end{array}$$

Chlorosulphuric acid.

$$\begin{array}{ll} \mathrm{H} & \\ & \}\mathrm{O} \\ (C^2H^4)'' & \\ & \}\mathrm{O} \\ (C^2H^4)'' & \\ & \}\mathrm{O} \\ \mathrm{H} & \end{array}$$

Diethylenic alcohol ($= C^4H^{10}O^3$).

$$\begin{array}{ll} \mathrm{K} & \\ & \}\mathrm{O} \\ (S)'' & \\ & \}\mathrm{O} \\ (S)'' & \\ & \}\mathrm{O} \\ \mathrm{K} & \end{array}$$

Hyposulphite of potassium ($= S^2K^2O^3$).

$$\begin{array}{ll} \mathrm{H} & \\ & \}\mathrm{O} \\ (C^2H^4)'' & \\ & \}\mathrm{O} \\ (C^2H^4)'' & \\ & \}\mathrm{O} \\ (C^2H^4)'' & \\ & \}\mathrm{O} \\ (C^2H^4)'' & \\ & \}\mathrm{O} \\ (C^2H^4)'' & \\ & \}\mathrm{O} \\ \mathrm{H} & \end{array}$$

Pentethylenic alcohol ($= C^{10}H^{22}O^6$).

$$\begin{array}{ll} \mathrm{K} & \\ & \}\mathrm{O} \\ (S)'' & \\ & \}\mathrm{O} \\ (S)'' & \\ & \}\mathrm{O} \\ (S)'' & \\ & \}\mathrm{O} \\ (S)'' & \\ & \}\mathrm{O} \\ (S)'' & \\ & \}\mathrm{O} \\ \mathrm{K} & \end{array}$$

Pentathionate of potassium ($= S^5K^2O^6$).

After these remarks, and what has been previously said about the combinations of polyatomic elements and radicles in general, the following table will be intelligible without further explanation. It gives a list (probably almost complete) of the known compounds containing two or more atoms of the same carbonated radicle, and a few examples of compounds containing radicles composed of other elements, such as sulphuryl (SO^2) and phosphoryl (PO). Many other examples of compounds of a similar nature might be found among mineral substances both natural and artificial, and there can be little doubt that the complex silicates and other minerals belong to this class of compounds. In the table, compounds of the same radicle are arranged on the same horizontal line; those referable to the same type are arranged in the same vertical column.

Classification according to Types (continued).

	Compounds referable to the type H^6O^3.	Compounds referable to the type H^8O^4.	Compounds referable to the type $H^{10}O^5$.	Compounds referable to the type $H^{12}O^6$.	Compounds referable to the type $H^{14}O^7$.	Compounds referable to the type $\left.\begin{matrix}H^8O^4\\HCl\end{matrix}\right\}$.	Compounds referable to the type $\left.\begin{matrix}H^4O^2\\H^3N\end{matrix}\right\}$	Compounds referable to the type $\left.\begin{matrix}H^6O^3\\H^3N\end{matrix}\right\}$.	Compounds referable to the type $\left.\begin{matrix}H^4O^2\\HCl\\H^3N\end{matrix}\right\}$.
Compounds containing the radicle *ethylene*, $(C^2H^4)''$.	$\left.\begin{matrix}(C^2H^4)^2\\H^2\end{matrix}\right\}O^3$ Lourenço.	$\left.\begin{matrix}(C^2H^4)^3\\H^2\end{matrix}\right\}O^4$ Wurtz, Lourenço.	$\left.\begin{matrix}(C^2H^4)^4\\H^2\end{matrix}\right\}O^5$ Wurtz Lourenço.	$\left.\begin{matrix}(C^2H^4)^5\\H^2\end{matrix}\right\}O^6$ Wurtz, Lourenço.	$\left.\begin{matrix}(C^2H^4)^6\\H^2\end{matrix}\right\}O^7$ Lourenço.		$\left.\begin{matrix}(C^2H^4)^2\\H^3\end{matrix}\right\}\begin{matrix}O^2\\N\end{matrix}$ Wurtz.	$\left.\begin{matrix}(C^2H^4)^3\\H^3\end{matrix}\right\}\begin{matrix}O^3\\N\end{matrix}$ Wurtz.	
Compounds containing the radicle *glycolyl*, $(C^2H^2O)''$.	$\left.\begin{matrix}(C^2H^2O)^2\\H^2\end{matrix}\right\}O^3$ Wurtz, Heintz	$\left.\begin{matrix}(C^2H^2O)^2\\(C^2H^4)H^2\end{matrix}\right\}O^4$ Wurtz.							
Compounds containing the radicle *lactyl*, $(C^3H^4O)''$.	$\left.\begin{matrix}(C^3H^4O)^2\\H^2\end{matrix}\right\}O^3$ Pelouze. $\left.\begin{matrix}(C^3H^4O)^2\\(C^2H^5)H\end{matrix}\right\}O^3$ Wurtz and Friedel.	$\left.\begin{matrix}(C^3H^4O)^3\\(C^2H^5)H\end{matrix}\right\}O^4$ Wurtz and Friedel. $\left.\begin{matrix}(C^3H^4O)^3\\(C^2H^5)^2\end{matrix}\right\}O^4$ Wurtz and Friedel. $\left.\begin{matrix}(C^3H^4O)^2\\(C^4H^4O^4)^2\\(C^2H^5)^2\end{matrix}\right\}O^4$ Wurtz & Friedel.							
Compounds containing the radicle *anisalyl*, $(C^8H^8)''$.							$\left.\begin{matrix}(C^8H^8)^2\\H^3\end{matrix}\right\}\begin{matrix}O^2\\N\end{matrix}$ Cannizzarro.		
Compounds containing the radicle *sulphuryl*, $(SO^2)''$.	$\left.\begin{matrix}(SO^2)^2\\H^2\end{matrix}\right\}O^3$ (Nordhausen sulphuric acid).						$\left.\begin{matrix}(SO^2)^2\\(C^6H^5)H^2\end{matrix}\right\}\begin{matrix}O^2\\N\end{matrix}$ Carius. $\left.\begin{matrix}(SO^2)^2\\(C^7H^7)H^2\end{matrix}\right\}\begin{matrix}O^2\\N\end{matrix}$ Carius. $\left.\begin{matrix}(SO^2)^2\\(C^9H^{11})H^2\end{matrix}\right\}\begin{matrix}O^2\\N\end{matrix}$ Carius.		
Compounds containing the radicle *glyceryl*, $(C^3H^5)'''$.		$\left.\begin{matrix}(C^3H^5)^2\\H^2\end{matrix}\right\}O^4$ Lourenço.	$\left.\begin{matrix}(C^3H^5)^2\\H^4\end{matrix}\right\}O^5$ Lourenço. $\left.\begin{matrix}(C^3H^5)^2\\(C^2H^5)^3H\end{matrix}\right\}O^5$ Reboul and Lourenço.	$\left.\begin{matrix}(C^4H^5)^3\\H^3\end{matrix}\right\}O^6$ Lourenço.	$\left.\begin{matrix}(C^3H^5)^3\\H^5\end{matrix}\right\}O^7$ Lourenço. $\left.\begin{matrix}(C^3H^5)^3\\(C^2H^5)^4H\end{matrix}\right\}O^7$ Reboul and Lourenço.	$\left.\begin{matrix}(C^3H^5)^2\\(C^2H^5)^2\\H\end{matrix}\right\}\begin{matrix}O^4\\Cl\end{matrix}$ Reboul and Lourenço.			$\left.\begin{matrix}(C^3H^5)^2\\H^2\end{matrix}\right\}\begin{matrix}O^2\\Br\\N\end{matrix}$ Berthelot and de Luca.
Compounds containing the radicle *phosphoryl*, $(PO)'''$.		$\left.\begin{matrix}(PO)^2\\Na^2\end{matrix}\right\}O^4$ Maddrell. (Insoluble metaphosphate.)	$\left.\begin{matrix}(PO)^2\\Na^4\end{matrix}\right\}O^5$ Clark. (Pyrophosphate.)	$\left.\begin{matrix}(PO)^3\\Na^3\end{matrix}\right\}O^6$ Fleitmann and Henneberg.					

Classification according to Types (continued).

	Compounds referable to the type H^9N^3.	Compounds referable to the type $H^{12}N^4$.
Compounds containing the radicle *ethylene*, $(C^2H^4)''$ (*continued*).	$\left.\begin{matrix}(C^2H^4)^2\\ H^5\end{matrix}\right\}N^3$	$\left.\begin{matrix}(C^2H^4)^3\\ H^6\end{matrix}\right\}N^4$
	$\left.\begin{matrix}(C^2H^4)^2\\ (C^2H^5)^2\\ H^3\end{matrix}\right\}N^3$	$\left.\begin{matrix}(C^2H^4)^3\\ (C^2H^5)^6\end{matrix}\right\}N^4$
	$\left.\begin{matrix}(C^2H^4)^2\\ (C^2H^5)^3\\ H^2\end{matrix}\right\}N^3$	$\left.\begin{matrix}(C^2H^4)^5\\ (C^2H^5)^2\end{matrix}\right\}N^4$
	$\left.\begin{matrix}(C^2H^4)^3\\ H^3\end{matrix}\right\}N^3$	$(C^2H^4)^6N^4$
	$\left.\begin{matrix}(C^2H^4)^3\\ (C^2H^5)^3\end{matrix}\right\}N^3$	
	Hofmann.	Hofmann.

A little reflection upon what has been said (p. 1017) on the nature of compound radicles, and on the sense in which they are employed, will make it clear that a classification of compounds by means of them, according to types, such as that illustrated in the two tables given, pp. 1018, 1019, 1021, 1022, expresses all we know of their general chemical properties. For the classification of a number of substances as containing the same radicle, expresses that they are mutually convertible by comparatively simple processes, that is, that they are *genetically* related,—while the classification of any set of bodies by reference to the same type, expresses that they are capable of undergoing similar transformations, and are therefore *functionally* related. All our strictly chemical knowledge, however, consists in a knowledge (1) of the nature and proportion of the elements of which substances are composed; (2) of their genetic relations, or of the bodies from which they can be formed, or to which they can give rise; and (3) of their chemical functions, or the transformations which they cause or undergo when they react with other bodies. In the foregoing pages, we have accordingly endeavoured to point out the leading principles which must be kept in view in classifying chemical substances with reference to considerations of each of these three kinds, considering however at the greatest length the classification of bodies according to their composition; partly because much less attention has been paid to this subject, in the existing literature of chemistry, than to their genetic and functional relations, but chiefly because composition is the most fundamental of all chemical properties, and the manner in which all other chemical properties depend upon it is the fundamental problem of chemistry. Throughout, we have endeavoured to distinguish between ideas and mere forms of expression, rendered convenient by the existing state of the science.

The order and system which has been followed in this article, has made it impossible to trace the historical development of the ideas therein set forth. The following list of Memoirs of theoretical importance will be of assistance to such readers as wish to trace that development from the birth of Organic Chemistry to the present time; many other memoirs of equal importance with some of those enumerated, might have been quoted; but in a large number of these, references are given which will serve as a guide to those who wish to pursue the subject further.

CLAUSTHALITE. Native selenide of lead. (See Lead.)

CLAY. This term is applied to hydrous silicates of aluminium, produced for the most part by the decomposition of felspar rocks, and generally mixed with small quantities of other substances, chiefly lime, magnesia, and oxide of iron. The clays exhibit the following general characters:—They are opaque, non-crystallised bodies, sufficiently soft to be scratched by iron; they have a dull or even earthy fracture; they exhale, when breathed on, a peculiar smell called argillaceous. The clays form with water a plastic paste, possessing considerable tenacity, which hardens with heat, so as to strike fire with steel. Marls and chalks also soften in water, but their paste is not tenacious, nor does it acquire a siliceous hardness in the fire. The affinity of the clays for moisture is manifested by their sticking to the tongue, and by the intense heat necessary to make them perfectly dry. Those which contain iron turn red when burnt. Clay is often mixed with quartz, and contains fine particles of felspar, mica, and beryl, showing that it has been produced by the decomposition of felspar or granite.

The principal varieties of clay are the following:

1. *Porcelain earth*, the kaolin of the Chinese.—This mineral is friable, meagre to the touch, and, when pure, forms with difficulty a paste with water. It is infusible in a porcelain furnace. It is of a pure white, verging sometimes upon the yellow or flesh-red. Some varieties exhibit particles of mica, which betray their origin to be from felspar or graphite granite. Porcelain clay scarcely adheres to the tongue. Specific gravity 2·2. The average composition of kaolin, when separated from free silica and undecomposed felspar, is 47 per cent. silica, 40 alumina, and 13 water, agreeing with the formula $Al^4O^3.2SiO^2 + 2$ aq. It may be supposed to be formed from orthoclase, $K^2O.Al^4O^3.6SiO^2$, by abstraction of the whole of the potash and $\frac{2}{3}$ of the silica, and addition of 2 at. water. Some varieties, however, exhibited a different composition; thus the kaolin of Passau contains, according to Fuchs, 43·65 per cent. SiO^2, 35·93 Al^4O^3, 1·00 Fe^4O^3, and 18·50 water, besides 0·88 carbonate of calcium, a composition which may be approximately represented by the formula $4Al^4O^3.9SiO^2 + 12$aq. Porcelain clay from Gutenberg, near Halle, contains, according to Bley, 39·02 SiO^2, 45·00 Al^4O^3, and 10·00 water, together with 0·07 carbonate of calcium, 3·32 carbonate of magnesium, and 0·19 sesquioxide of iron, agreeing approximately with $2Al^4O^3.3SiO^2 + 3$aq. (*Rammelsberg's Mineralchemie*, p. 574). In two specimens of Chinese kaolin, Ebelmen and Salvétat (Ann. Ch. Phys. xxxi. 257) found 73·4 and 80·7 SiO^2, 44·5 Al^4O^3, 14·4 and 12·0 water; in these the quantity of silica is twice as great, in proportion to the alumina, as in the ordinary formula of kaolin (Dana, ii. 250). Kaolin is found in primitive mountains, amid blocks of granite, forming interposed strata. Kaolins are sometimes preceded by beds of a micaceous rock of the texture of gneiss, but red and very friable. This remarkable disposition has been observed in the kaolin quarries of China, in those of Alençon,and of St. Yrieux, near Limoges. The Chinese and Japanese kaolins are whiter and more unctuous to the touch than those of Europe. The Saxon has a slight tint of yellow or carnation, which disappears in the fire, and therefore is not owing to metallic impregnation. At St. Yrieux, the kaolin is in a stratum, and also in a vein, amid blocks of granite, or rather the felspar rock which the Chinese call *petuntze*. The Cornish kaolin is very white and unctuous to the touch, and is obviously formed by the disintegration of the felspar of granite.

2. *Potters' clay*, or *plastic clay*.—The clays of this variety are compact, smooth, and almost unctuous to the touch, and may be polished by the finger when they are dry. They have a great affinity for water, form a tenacious paste, and adhere strongly to the tongue. The paste of some is even slightly transparent. They acquire great solidity, but are infusible in the porcelain furnace. This property distinguishes them from the common clays employed for coarse earthenware. Some of them remain white, or become so in a high heat; others turn red. Specific gravity about 2. The slaty potters' clay of Werner has a dark ash-grey colour; principal fracture imperfectly conchoïdal, cross fracture earthy; fragments tabular, rather light; it feels more greasy than common potters' clay. Vauquelin's analysis of the plastic clay of Forges-les-Eaux, employed for making glass-house pots, as well as pottery, gave 16 alumina, 63 silica, 1 lime, 8 iron, and 10 water. Another potters' clay gave 33·2 and 43·5, of alumina and silica, with 3·5 lime.

Fire-clay is a very refractory plastic clay, much used in the manufacture of fire-bricks, glass-house pots, &c. In this country it lies immediately beneath the coal, each bed of which rests upon a stratum of this clay, hence called in the mining districts *under-clay*. The Stourbridge clay is of this character. (See FIRE-CLAY.)

3. *Loam*.—This is an impure potters' clay mixed with mica and iron ochre. Colour yellowish-grey, often spotted yellow and brown. Massive, with a dull glimmering lustre from scales of mica. Adheres pretty strongly to the tongue, and feels slightly greasy. Its density is inferior to the preceding.

4. *Variegated clay* is striped or spotted with white, red, or yellow. Massive, with an earthy fracture, verging on slaty. Shining streak. Very soft, sometimes even friable. Feels slightly greasy, and adheres a little to the tongue. Sectile. It is found in Upper Lusatia.

5. *Slate clay*.—Colour grey, or greyish-yellow. Massive. Lustre dull or glimmering from interspersed mica. Fracture slaty, approaching sometimes to earthy. Fragments tabular. Opaque, soft, sectile, and easily broken. Specific gravity 2·6. Adheres to the tongue, and breaks down in water. It is found along with coal, and in the floetz trap formation.

6. *Claystone.*—Colour grey, of various shades, sometimes red, and spotted or striped. Massive. Lustre dull, with a fine earthy fracture, passing into fine-grained uneven, slaty, or splintery. Opaque, soft, and easily broken. Does not adhere to the tongue, and is meagre to the touch. It has been found on the top of the Pentland hills in Scotland, and in Germany.

7. *Adhesive slate.*—Colour light greenish-grey. Internal lustre dull; fracture in the large, slaty; in the small, fine earthy. Fragments slaty. Opaque. Streak shining. Sectile. Easily broken or exfoliated. Adheres strongly to the tongue, and absorbs water rapidly, with emission of air bubbles and a crackling sound. It is found at Montmartre, near Paris, between blocks of impure gypsum, in large straight plates like sheets of pasteboard; also at Menilmontant, enclosing menilite. Klaproth's analysis gives 62·5 silica, 8 magnesia, 0·5 alumina, 0·25 lime, 4 oxide of iron, 22 water, and 0·75 charcoal. Its specific gravity is 2·08.

8. *Polishing slate* of Werner.—Colour cream-yellow, in alternate stripes. Massive. Lustre dull. Slaty fracture. Fragments tabular. Very soft, and adheres to the tongue. Smooth, but meagre to the touch. Specific gravity in its dry state 0·6; when imbued with moisture 1·9. It has been found only in Bohemia. Its constituents are, 79 silica, 1 alumina, 1 lime, 4 oxide of iron, and 14 water.

9. *Common clay* may be considered to be the same as *loam.*—Besides the above, we have the analyses of some pure clays, the results of which show a very minute quantity of silica, and a large quantity of sulphuric acid. Thus, in one analysed by Bucholz, there was 1 silica, 31 alumina, 0·5 lime, 0·5 oxide of iron, 21·5 sulphuric acid, 45 water, and 1·5 loss. Simon found 19·35 sulphuric acid in 100 pts. These clays must be regarded as basic sulphates of aluminium. U.

For analysis of various clays, see *Ure's Dictionary of Arts, Manufactures and Mines,* i. 691.

CLAY-SLATE. *Argillaceous schist;* the *Argillite* of Kirwan.—Colour bluish-grey and greyish-black of various shades. Massive. Internal lustre shining or pearly. Fracture foliated. Fragments tabular. Streak greenish-white. Opaque. Soft. Sectile. Easily broken. Sonorous when struck with a hard body. Specific gravity 2·7. Its constituents are 48·6 silica, 23·5 alumina, 1·6 magnesia, 11·3 sesquioxide of iron, 0·5 oxide of manganese, 4·7 potash, 0·3 carbon, 0·1 sulphur, 7·6 water and volatile matter. Clay-slate melts easily before the blowpipe into a shining scoria. This mineral is extensively distributed, forming part of both primitive and transition mountains. The great beds of it are often cut across by thin seams of quartz or carbonate of lime, which divide them into rhomboïdal masses. Good slates should not imbibe water. If they do, they soon decompose by the weather. U.

CLAY IRON-STONE. See Iron.

CLAYITE. A mineral from Peru, occurring crystallised and as a crust $\frac{3}{8}$ of an inch thick on quartz. It appears to be composed of the sulpharsenites of copper and sulphantimonites of copper and lead. The crystals belong to the regular system, being combinations of the tetrahedron with the rhombic dodecahedron. Colour blackish-grey. Streak the same. Lustre metallic. Hardness = 2·5. Sectile. Melts easily before the blowpipe, and gives the reactions of lead, arsenic, and antimony. With soda it yields a metallic globule, which becomes dull on cooling. Possibly a pseudomorph of fahl-ore. (W. J. Taylor, Sill. Am. J. [2] xxix. 367.)

CLEAVAGE OF CRYSTALS. See Crystallography.

CLEAVLANDITE. Soda-felspar. (See Felspar.)

CLEOPHANE. Syn. with blende or native sulphide of zinc. (See Zinc).

CLEMATIS-CAMPHOR. The young branches of *Clematis flammula, Cl. vitalba, Cl. viticella, Cl. erecta,* &c., yield by distillation with water, a liquid which has a sharp taste, a pungent odour of radish, and reddens the skin; when exposed to the air, it loses its acidity, and if left to stand in closed vessels, deposits white scales and flocks of clematis-camphor. (Braconnot, Ann. Ch. Phys. vi. 734.)

CLEMATITIN. A bitter substance, perhaps $C^9H^{10}O^6$, obtained by Walz from the root of *Aristolochia clematitis* (i. 357).

CLINGMANNITE. Syn. with Margarite (*q. v.*)

CLINKSTONE or **PHONOLITE** is a compact felspathic rock, of greyish colour and smooth fracture, clinking when struck with a hammer, somewhat like a metal. Specific gravity = 2·2 – 2·4.

CLINOCHLORE. A mineral having the same composition as chlorite (i. 913), but differing from it in crystalline form, inasmuch as it belongs to the trimetric system, whereas chlorite is rhombohedral. The crystals of clinochlore are hemihedral, and have a micaceous structure, the crystallising planes often forming equilateral triangles. It is optically biaxial, the angle between the axes being 84° 30′ (or 80° to 86°); the plane of the axes is perpendicular to the cleavage-surface, but the two axes are unequally inclined to this surface, one at 54° the other at 30°. It occurs in large crystals, usually having a rhombohedral aspect, and in plates; often compounded, the crystals giving a second pair of optical axes, making an angle of 60° with the other. Specific gravity about 2·714. Hardness 2—2·5. Lustre somewhat pearly. Colour olive-green. Transparent, unless in thick plates. Somewhat elastic.

Analyses.—*a*, *b*, from Chester county, Pennsylvania, by W. J. Craw (Sill. Am. J. [2] xiii. 222); *c*, from Lisgau, Bavaria, Kobell (Gel. Anzeige, 1854, No. 43):

	SiO^2	Al^4O^3	Fe^4O^3	Cr^4O^3	Mg^2O	H^2O		
a.	31·34	17·47	3·85	1·69	33·44	12·60		= 100·39
b.	31·78		22·71		33·64	12·60		= 100·72
c.	33·49	15·87	2·30	0·55	32·94	11·50	Fe^2O 4·25	= 100·40

Before the blowpipe it behaves like chlorite, showing traces of fusion on the edges. (Dana, ii. 294.)

CLINOCLASE. Syn. with ABICHITE (i. 1).

CLINTONITE. *Seybertite, Holmesite, Chrysophane.*—A silicate found at Amity, New York, in limestone connected with serpentine, together with augite, hornblende, spinel, and graphite. It forms small tabular crystals or foliated masses, sometimes lamellar, radiate. Structure thin, foliated, or micaceous, parallel to the base. According to Breithaupt, the crystals are monoclinic, with the angles between the lateral planes = 94°. Specific gravity = 3—3·1. Hardness = 4—5. Lustre pearly, submetallic. Colour reddish-brown, yellowish or copper-red. Streak uncoloured, or slightly yellowish or greyish. Folia brittle.

Closely allied to clintonite are *Xanthophyllite*, from Slatoust in the Ural, where it occurs in implanted globules, and in columnar or lamellar individuals, sometimes enclosing small hexagonal crystals secondary to a rhombic prism, and *Disterrite* or *Brandisite*, occurring in the Fassa valley, Tyrol, in hexagonal prisms of specific gravity 3·042—5·051, and hardness = 5 on the base, 6—6·5 on the sides.

Analyses.—*a*, *Seybertite*, by Clemson (Sill. Am. J. xxiv. 171).—*b*, *Holmesite*, by Richardson (Rec. Gen. Sci. May, 1836).—*c*, Clintonite, by Brush (Sill. Am. J. [2] xviii. 407).—*d*, *Xanthophyllite*, by G. Rose (Pogg. Ann. i. 654).—*d*, *Disterrite* or *Brandisite*, by Kobell (J. pr. Chem. xli. 154):

	SiO^2	ZrO^2	Al^4O^3	Fe^4O^3	Mn^2O	Mg^2O	Ca^2O	K^2O	Na^2O	H^2O	F	
a.	17·0	—	37·6	5·5	—	24·3	10·7	—	—	3·6	—	= 99·7
b.	19·35	2·05	44·75	4·80	1·35	9·05	11·45	—	—	4·55	0·90	= 98·25
c.	20·18	0·19	38·90	3·87	—	21·25	13·52	0·29	1·14	1·04	—	= 100·41
d.	16·30	—	43·95	2·91	—	19·31	13·26	—	0·61	4·33	—	= 100·57
e.	20·00	—	43·22	3·60	—	25·01	4·00	0·57	—	3·60	—	= 100

These results may be approximately represented by the following formulæ, in which M denotes a uni-equivalent and R a sesquiequivalent metal:—

Clintonite (Seybertite, Holmesite) . $2M^2O.3SiO^2 + 2(3M^2O.2R^4O^3)$
Xanthophyllite . . . . . . $2M^2O.3SiO^2 + 3(3M^2O.2R^4O^3) + 3aq.$
Disterrite . . . . $2M^2O.3SiO^2 + 4(M^2O.R^4O^3) + 2aq.$

It is doubtful whether either of these minerals has been found in an unaltered state.

Clintonite is infusible before the blowpipe, but loses its brown colour and becomes opaque; heated in a flask it gives off neutral water. It is completely decomposed by hydrochloric acid.

Xanthophyllite yields green glasses with fluxes: it is decomposed by acids, like clintonite, but much less easily.

Disterrite when heated gives off water, which is neutral or alkaline, according as the specimen is fresh or has turned red-brown by weathering. Before the blowpipe it becomes turbid and greyish-white, but does not fuse; with fluxes it gives the reactions of iron and silica. It is not sensibly attacked by hydrochloric acid; but sulphuric acid decomposes it when heated with it for some time. (*Rammelberg's Mineralchemie*, p. 848.—Dana, ii. 297.)

CLOUDS are masses of air which contain innumerable minute particles of suspended water condensed from a state of vapour, and thus assume the appearance of white or misty bodies. The forms of clouds, which of course depend on the form and motions of the mass of air, were first properly classified by Howard, (*Rees' Cyclopædia*, art. CLOUD; *Nicholson's Journal*, 1811, xxx. 35—62; or *Howard's Climate of London*, 2nd ed. vol. i.), whose arrangement we may thus shortly describe.

Cirrus.—Parallel, flexuous, or diverging fibres, commonly called *mare-tails*, occurring most distinctly in the higher regions of the atmosphere, but sometimes originating from large masses of other cloud at lower elevations. The adjective *cirrose* may be applied to any streaked appearance in clouds.

Cumulus.—Convex or conical heaps, increasing upward from a horizontal base. This is the most abundant form of cloud, generally appearing during the day at a moderate elevation, and moving along with the current next the earth.

Stratus.—A widely extended continuous horizontal sheet, either lying upon the surface of the earth as a mist, or elevated at any height in the atmosphere.

Cirrostratus.—Stratus streaked with the fibres of the cirrus. This form of cloud, generally occurring at a great elevation, and consisting, therefore, of particles of ice, is the cause of solar and lunar halos, and also of the parhelion and paraselene.

Cumulostratus.—A cumulus the summit of which spreads laterally, producing an anvil-shaped cloud. This kind of cloud is very likely to turn to the following:

Nimbus, Cumulo-cirro-stratus, Rain, or *Thundercloud* is a cloud or system of clouds forming a great sheet or mass, mostly cumulose, but with lateral stratose extensions, and with tufts of cirrus spreading from the summit. It indicates a great disturbance of the atmosphere, caused by a violent upward current in the centre of the cloud, and is generally accompanied by wind or squalls.

The following further statements are on the authority of Howard.

The *cumulus* has the densest structure, and is formed in the lower atmosphere. A small irregular spot first appears, and is, as it were, the nucleus on which the mass increases. The lower surface continues irregularly plane, while the upper rises into conical or hemispherical heaps, which may afterwards long continue nearly of the same bulk, or rapidly rise into mountains. They will begin, in fair weather, to form some hours after sunrise, arrive at their maximum in the hottest part of the afternoon, then go on diminishing, and totally disperse about sunset. Previous to rain, the cumulus increases rapidly, appears lower in the atmosphere, and with its surface full of loose fleeces or protuberances. The formation of large cumuli to leeward in a strong wind indicates the approach of a calm with rain. When they do not disappear or subside about sunset, but continue to rise, thunder is to be expected in the night.

The *stratus* has a mean degree of density, and is the lowest of clouds, its inferior surface commonly resting on the earth or water. This is properly the cloud of night, appearing about sunset. It comprehends all those creeping mists, which in calm weather ascend in spreading sheets (like an inundation of water), from the bottom of valleys and the surfaces of lakes and rivers. On the return of the sun, the level surface of this cloud begins to put on the appearance of cumulus, the whole at the same time separating from the ground. The continuity is next destroyed, and the cloud ascends and evaporates, or passes off with the appearance of the nascent cumulus. This has long been regarded as a prognostic of fair weather.

The *cirrus* having continued for some time increasing or stationary, usually passes either to the cirro-cumulus or the cirro-stratus, at the same time descending to a lower station in the atmosphere. This modification forms a very beautiful sky, is frequent in summer, and attendant on warm and dry weather. The *cirro-stratus*, when seen in the distance, frequently gives the idea of shoals of fish. It precedes wind and rain, is seen in the intervals of storms, and sometimes alternates with the cirro-cumulus in the same cloud, when the different evolutions form a curious spectacle. A judgment may be formed of the weather likely to ensue, by observing which modification prevails at last.

Howard did not explain the special causes of forms of clouds above described, nor can we point to more than one or two attempts at all sound and scientific to accomplish this. In two papers, however, in the *Philosophical Magazine* (4th ser. xiv. 22; xv. 241), it is shown, by analogical experiments with liquids, that the cirrus arises from the *interfiltration* of masses of air saturated with moisture, and not in equilibrium; the stratus, from mixture or contact of layers of air tranquilly moving on or lying over each other, while the cumulus arises from the violent ascent of columns of air in the atmosphere. The nimbus, rain, or thundercloud appears to be formed in like manner.

Very little is known of the nature of clouds from which slow long-continued rain falls, as it so commonly does in London, but the cloud is probably for the most part stratose.

More particular accounts of the phenomena of the clouds and weather must be sought in works on meteorology, among which by far the most philosophical and reliable, is Sir J. Herschel's Essay on Meteorology (Encyc. Brit. 8th ed.). To this Essay we are indebted for some of the following remarks.

It is more within the province of the chemist to consider the nature of the *matter* of clouds. Meteorologists have generally assumed, as an unsupported dogma, that cloud particles are small vesicles or watery bubbles. Saussure, indeed, is said to have examined these vesicles in the mists of high mountains, and to have found them vary in size from $\frac{1}{4500}$ inch to the $\frac{1}{2780}$ inch, occasionally however attaining the size of a pea. Now although no observer is in general more deservedly trusted than Saussure, his unsupported announcements must not always be adopted as conclusive, and we are quite unaware of any one else having witnessed vesicles of appreciable size floating in the air and forming clouds or mists. It is also stated (*Graham's Elements*, 2nd ed. i. 314), that the vesicles may be observed by a lens of an inch focal length, over the dark surface of hot tea or coffee, mixed with an occasional solid drop, which contrasts with them. Having tried this, we witnessed a white dust of watery particles of uniform size, blowing about over the surface of the coffee, or rising in little wreaths and whirlwinds like dust on a windy day, but we saw no drops appearing solid as contrasted with the rest, and were inclined to consider them all solid particles of about the diameter of $\frac{1}{5000}$ inch. No one has ever suggested how the vesicles are formed, nor is it easy to conceive any possible mode of their formation.

In favour of the vesicular theory, it may be urged that rainbows are at least very seldom produced when the sun shines on cloud or on steam, although a rainbow is exhibited under such circumstances by the minutest rain and by spray from a fountain or waterfall. Sir J. Herschel suggests that the particles may be of an *order of smallness* comparable to the lengths of the light-undulations, which are on an average about $\frac{1}{50000}$ inch long. Hence, he infers, the refractions and reflections of light which cause the rainbow would not take place. (See also Raillard, *Comptes Rendus*, xliii. 906.)

The existence of vesicular vapour of water seems, however, to have been disproved by the microscopic observations of Dr. A. Waller (Phil. Trans. cxxxvii. [1847] p. 23), which later writers have overlooked. Steam being thrown upon a surface of Canada balsam, the particles of water became fixed and were easily examined in the microscope. It was concluded that whenever we are enabled to inspect the minutest particles of water arising from condensed steam or vapours, they consist of minute liquid globules without any appearance of internal cavity.

The suspension of the clouds is in no way mysterious, and arises only from the enormous comparative resistance which the air offers to the motion of a very minute body, as Prof. Stokes has lately shown (Cambridge Phil. Trans. vol. viii. ix.) A globule of water of the diameter of $\frac{1}{1000}$ inch, in falling through the air, would have the maximum velocity of about ·067 inch per second, which is quite inappreciable compared with the ascensional movement of the air, which is generally taking place in all large masses of cloud. The watery particles, or the air, generally both, must then be in motion in every cloud. (See also Phil. Trans. vol. lv. [1765] p. 162.)

No satisfactory reason has ever been given why the clouds only sometimes discharge rain, but it is not difficult to see that if all the particles were of equal size, they would all subside at exactly the same rate, and no collisions could take place. But if a further set of particles were precipitated of a different size they would move at a different rate, and encounter the other particles; many particles would thus coalesce into drops of sufficient size to fall rapidly, and receiving accretions in their passage through the air, reach the surface of the earth as rain. The coalescence of minute globules vastly diminishes their surface as compared with their bulk; it is easy then to understand how electric tension existing on the surface of cloud particles is so intensified when rain falls as to occasion lightning. This theory of the thundercloud was suggested as early as 1752 by Eeles (Phil. Trans. p. 527), and it is repeated in the papers in the *Philosophical Magazine* before referred to.

There are two principal ways in which cloud particles are produced:

1. A gas in changing its volume also changes its temperature, and may thus be unable to sustain in the gaseous state all the aqueous vapour which is diffused through it. Thus, if the air within the receiver of an air-pump be moist, a few strokes of the pump will produce a visible mist. In the atmosphere, by far the largest masses of clouds are thus produced by columns of air rising, and consequently expanding and growing cold as they rise. Fogs, it is also said, may be produced at the surface by sudden changes of barometric pressure.

2. Two masses of moist air of different temperatures will not, when mixed, sustain the whole of the contained vapour in the gaseous state: for the maximum tension of aqueous vapour varies in a higher ratio than the temperature. Hence the mean tension of vapour on mixing, will always be higher than the tension possible at the mean temperature, and vapour will be condensed until the two are equalised. Thus arise the cirrose and stratose forms of cloud, from the mixing of bodies of air under various circumstances.

Gases have but an inappreciable power of conducting heat. A cold surface may indeed condense vapour from the air, as in the formation of dew, but the water condensed will all attach itself to the cold surface, and no cloud-particles will be produced.

Dr. Tyndall having lately proved that gases may radiate heat, it is possible that clouds may be produced in the higher parts of the atmosphere by slow radiation. W. S. J.

CLOVES, OIL OF. *Gewürznelkenöl.*—This oil, obtained by distilling with water the buds and flower-stalks of the clove-tree, *Eugenia caryophyllata*, or *Caryophyllus aromaticus*, L., is a mixture of eugenic acid (*q. v.*) and a hydrocarbon, $C^{10}H^{16}$, isomeric with oil of turpentine. This hydrocarbon passes over with vapour of water, when the crude oil of cloves is distilled with potash-ley. It is highly refractive, has a density of 0·918 at 18° C., and boils at 142°—143°. It is not attacked by alkalis; it absorbs a large quantity of hydrochloric acid, and without forming a crystalline compound (Ettling, Ann. Ch. Pharm. lx. 68). Water distilled from cloves sometimes deposits nacreous scales of eugenin, a substance probably isomeric with eugenic acid.

According to Stenhouse (Ann. Ch. Pharm. xcv. 103), the so-called oil of cinnamon-leaf is likewise a mixture of eugenic acid and a hydrocarbon, $C^{10}H^{16}$. It has a density of 0·862, and boils at 160°—165° C.; it contains also a small quantity of benzoic acid.

CLOVORUBRIN. A resinous body produced by the action of sulphuric acid on oil of cloves.

CLUB MOSS. See Lycopodium.

CLUTHALITE. A mineral related to analcime (p. 210), occurring in flesh-red vitreous crystals in the amygdaloïd of the Kilpatrick Hills. Specific gravity = 2·166. Hardness = 3·5. Opaque or subtranslucent. Fragile. Contains 51·27 SiO^2, 23·56 Al^4O^3, 7·31 Fe^4O^3, 5·13 Na^2O, 1·23 Mg^2O, and 10·55 water = 99·05. (Thomson, *System of Mineralogy*, i. 339.)

CNICIN. *Centaurin.* (Morin, J. Chim. méd. iii. 105; Scribe, Compt. rend. xv. 803).—A bitter substance contained in *Centaurea benedictus* or *Cnicus benedictus* (Morin); also in the leaves of *Centaurea calcitrapa*, and in all bitter plants of the order *Compositæ*, sub-order *Cynarocephalæ* (Scribe). Morin first obtained it in an impure state by treating the alcoholic extract of *Centaurea benedictus* with ether, evaporating, precipitating with sub-acetate of lead, evaporating the filtered liquid after freeing it from lead, and treating the residue with ether and alcohol. It was afterwards obtained by Nativelle and further examined by Scribe.

Cnicin forms white transparent silky needles, inodorous, having a pure bitter taste, and neutral reaction, easily soluble in alcohol and wood-spirit, very little soluble in ether. The alcoholic solution deflects the plane of a polarised ray to the right; $[\alpha] = +130{\cdot}68°$ (Bouchardat). It is nearly insoluble in cold water, dissolves somewhat more easily in warm water. The solution is decomposed by continued boiling, becoming turbid and afterwards depositing a viscid body like turpentine.

Cnicin gives by analysis 62·9 per cent. carbon, 7·0 hydrogen, and 30·1 oxygen, whence have been deduced the three formulæ $C^{14}H^{18}O^5$, $C^{20}H^{26}O^7$, and $C^{28}H^{34}O^9$. They all agree pretty nearly with the analysis, but as there is no means of determining the atomic weight of cnicin, it is impossible at present to decide between them.

Cnicin submitted to dry distillation gives off vapours and becomes carbonised. Strong sulphuric acid dissolves cnicin with deep blood-red colour, the liquid becoming black when heated. Strong hydrochloric acid is coloured green by it; if heat be applied, the liquid turns brown, and oily drops collect on its surface, solidifying in a resinous mass on cooling.

COAGULUM is a term applied to any viscid or curdy mass separated from a liquid, as cheese from milk, the clot from blood, &c.

COAL. *Houille. Steinkohle.*—The vast masses of fossil fuel which are stored up within the bowels of the earth, and in particular constitute so essential an element of our national prosperity, are undoubtedly the result of complex chemical changes, acting under varying circumstances of temperature, pressure, moisture, &c., either upon vegetable matter growing on the spot, or upon the remains of plants collected by the drift of rivers, &c., into particular localities.

The vegetable origin of coal is beyond doubt, nor can there be any question as to the character of the flora of the carboniferous era, about 500 distinct species, including 250 ferns, having been recognised as belonging to that period.

The discovery of distinct ligneous structure in most kinds of coal appears, however, to be somewhat questionable; and although Bischof and others have entered into interesting and highly valuable speculations as to the precise changes, by virtue of which woody matter may be converted into coal, the microscopic and chemical examination of the substances themselves, do not afford direct *proof* of the accuracy of these conceptions.

The conversion of wood into coal, according to Bischof, may take place in four different ways, viz.:

1. By separation of carbonic acid and carburetted hydrogen.
2. " " " water.
3. " carburetted hydrogen and water.
4. " " " carbonic acid.

(For the formulæ representing these changes we refer the reader to *Bischof's Chemical and Physical Geology*, vol. i. p. 274, *et. seq.*)

"When wood or vegetable matter, then, is buried under circumstances which allow of the extrication of these substances from it, in the course of its decomposition, it *must* become converted into coal; the extreme result of the process being to give us, first anthracite, containing perhaps 94 per cent. of carbon, and finally graphite, which is either pure carbon itself, or that substance mingled with others which are here excluded from consideration, as not being among the elements of wood, and which it may have acquired from external sources during the process of conversion.

"The great quantities of carbonic acid gas (choke-damp), and carburetted hydrogen (fire damp) met with in coal mines, show the fact of the large extrication of these substances, and corroborates, if need were, this explanation. Reservoirs of these gases in a highly compressed state are often found to be pent up in the crevices and cavities of coal beds. Some beds of coal are so saturated with gas, that when they are cut into, it may be heard oozing from every pore of the rock, and the coal is called by the colliers 'singing coal.'" (Beete Jukes, *Manual of Geology.*)

The natural escape of light carburetted hydrogen, marsh-gas or fire-damp (CH^4), which frequently bursts forth in large quantities from the seams of coal or strata of fire-clay which divide them, is the frequent cause of those terrible accidents, of which the Lund Hill Colliery explosion in 1857, and the still more recent one at Burradon, have been the most calamitous upon record.

The sudden issue of gas from a *blower* in the colliery adjacent to that of Lund Hill is thus described. "The fire-clay of the floor of the seam was seen to heave at different points along the face, and presently large fractures were made in it, through which gas was ejected with great violence and with a sound very similar to the issue of steam at a high pressure from a boiler." Subsequent to the explosion at Lund Hill, the pent up gas still issuing within the mine in the higher parts of the workings supported two columns of water 30 feet high, one 10 feet and the other 11½ feet diameter, corresponding to a pressure of about 11 lbs. on the square inch. This gas in exploding renders unfit for respiration 10 times its own bulk of air: hence the "after damp" of the miner, the vitiated atmosphere produced by the explosion, often fatal to those working in other parts of the mine, or to those who descend into the pits without proper precautions, or until ventilation has been sufficiently re-established.

"The subjoined tables, given by Miller, give an idea of the composition of wood and will illustrate the progress of its decay. They also furnish a synoptic view of the composition of some of the principal varieties of coal, in the order of their occurrence in successive geological stages. The proportion of oxygen diminishes rapidly and that of hydrogen more slowly, as the coal passes from lignite towards anthracite, in which form it consists of nearly pure carbon."

Ash . . .	6·034	2·70	1·40	1·03	5·51	1·61

The composition of coals varies largely, not only in respect of the relative proportions of carbon, hydrogen, oxygen and nitrogen which they contain, but also of the amount of extraneous matters which constitute the impurities of fuel. These consist of a variable amount of mineral matters which remain after combustion of the coal, as ash or "clinker."

The percentage of ash ranges from about 1 to 30 or 35, and in some coals, which are considered too poor to be brought to market, to even more than this quantity.

It consists chiefly of silicate of alumina, with variable amounts of oxide of iron. Vaux found also in many coals traces of lead and copper.

"We have in nature every gradation, from pure coal into a mere carbonaceous (commonly called bituminous) shale or 'batt' which often contains enough imflammable matter to give out flame and support combustion for a time when burnt with better coals, but soon passes into a lump of ash, unaltered in form and not retaining heat longer than a brickbat would under similar circumstances." Accordingly, the composition of the ash of coals closely resembles that of the batts, shales, or fire-clays which usually occur, either as strata above or below the coal, or in their "partings" between the several layers of the coal itself.

The following table exhibits the amount and composition of the ashes of several coals, as compared with that of fire-clays and "batts":

Muspratt states that the ash of lignite varies from 1 to 60 per cent., averaging about 5, and that of bituminous coal 1 to 2 per cent. In addition to these substances, the mineral matter of coal contains a small but variable quantity of sulphur, not accounted for in the above analyses, but constituting a most important element as regards the value of fuel for domestic and technical uses. This remark applies more especially to the value of coals for metallurgical purposes, particularly for employment in the blast-furnace; the ironmaster, has learned to eschew such samples of ironstone as contain any considerable percentage of sulphur and phosphoric acid; but this precaution is wholly ineffectual, unless a like care be exercised in the selection of the fuel and fluxes which are to be introduced into the blast-furnace with the ore.

The presence of sulphur is equally detrimental in the manufacture of gas, some portion of it being always eliminated as sulphuretted hydrogen and bisulphide of carbon, the complete removal of which is a matter at once of great difficulty and of the highest necessity, while the frequent cases of spontaneous combustion of coals in the hold of vessels is probably due, in some measure, to the oxidation of the pyrites which they contain under the influence of a moist atmosphere.

A minor evil is the evolution, during combustion, of sulphurous acid, a gas which is not only noxious and hurtful to human life, but destructive to boilers, locomotive tubes, and so forth.

Some of the lower seams of the South Staffordshire coal beds, otherwise available as good fuel, are unused, because they contain an amount of sulphur which renders it impossible to bear the smell which they exhale during combustion; whence their local name of *stinking coal*.

The mean percentage of sulphur found in the government investigation, under Playfair and De la Beche, was as below:

Samples.	Coals.	Mean.
37	Welsh	1·42
8	Derbyshire	1·01
28	Lancashire	1·42
17	Newcastle	0·94
8	Scotland	1·45

The following are other determinations of sulphur in coals:—

„ bottom	2·57
Newport steam coal (Miller)	1·10
Anthracite, South Wales (Vaux)	·91

"The frequent occurrence of iron pyrites in coal shows that its formation at the cost of organic remains is a very frequent phenomenon. This formation of iron pyrites can only be explained by the presence of sulphates; and so far as it goes on in the sea, only by the decomposition of sulphate of calcium.

The minor varieties of coal are almost infinite in number, and it is said that full a hundred different kinds are sent into the London market. The following appears to be as satisfactory a classification of the more important kinds as is possible, together with an indication of their characteristic differences, and of the localities whence they are obtained:—

1. LIGNITE or BROWN COAL generally retains in some degree its lamellar and woody structure. Yields a powdery coke in the form of the original lumps. Brittle, burns readily, but often contains from 30 to 40 per cent. water.

Occurs in England chiefly at Bovey Heathfield, in Devonshire, where it has long been used as fuel in the local potteries; the supply is now, however, falling off. Its other chief localities are Westphalia, the Hessian States, Lower Austria, Russia, Spain, Portugal, Italy, the Upper Missouri Valley, New Brunswick (impregnated with copper), Greenland, China, and the Burmese Empire, and in Central America in the province of Panama.

2. BITUMINOUS or CAKING COALS.—The most extensively diffused and valuable of English coals. These are of various shades of brown and black, emit much gas on heating, and hence are prized as "gas-coals;" they leave a coke more or less lustrous and fused, or *caked* together. Their fracture is generally uneven and their lustre resinous. The coals of this class are subdivided into:

Caking Coal, which splinters on heating, but the fragments then fuse together into a semi-pasty mass. Its chief sources are the Newcastle and Wigan districts, along the banks of the Tyne and Wear, and the north of the Tees.

Cherry Coal or *Soft Coal*.—Lustre very bright. Does not fuse. Ignites well and burns rapidly. Occurs in Glasgow, Staffordshire, Derbyshire, Nottingham, Lancashire, &c.

Splint, Rough or *Hard Coal.*—Black, and of glistening fracture. Does not ignite readily, but burns up to a clear hot fire, constituting a good house coal. Occurs in the Glasgow field, in Shropshire, Leicestershire, Warwickshire, Derbyshire, and at Nottingham, and constitutes in particular the bulk of the great coalfields of North and South Staffordshire.

Cannel Coal; Parrot coal of Scotland.—Of dense, compact, and even fracture, conchoïdal in every direction. Takes a polish like jet. Splinters in the fire and burns clearly and brightly. The chief localities in Great Britain are Wigan, and other parts of Lancashire, West Glasgow, and in smaller quantities at Coventry. It is found also in Kentucky.

The various kinds of bituminous coal constitute also the bulk of the immense coalfields of North America, compared with which the most extensive fields of the Old World are insignificant. These are the Alleghany or Appalachian field, and those of Pennsylvania, Illinois, New Brunswick, and Nova Scotia. In South America they occur in the province of Chili. They compose also the south side of the South Wales basin; are found in Connaught and Ulster, and on the European continent in Belgium, France, Prussia, Sweden, Russia, and Spain. Finally, the great coal range of New South Wales is supposed to belong to this class.

4. ANTHRACITE. STONE-COAL or CULM.—The densest, hardest, and most lustrous of all varieties. Burns with very little flame or smoke, but gives great heat. Contains very little volatile matter. Splinters when heated, and ignites with difficulty. Colour deep black, fracture lamellar, parallel to the bed of the deposit, conchoïdal in the cross fracture. Applied successfully to smelting, and much valued as a steam coal in the navy. Its most extensive deposit occurs over vast tracts of North America, chiefly in Pennsylvania. It constitutes also a large portion of the yield of the northwest portion of the South Wales coalfield. A further deposit occurs over a tract of about 12½ miles in Devonshire, in the neighbourhood of Barnstaple Bay and Bideford. Its other situations are Leinster and Munster in Ireland, and some districts of France, Sweden, and Portugal.

5. STEAM COAL approaches nearly to anthracite. It does not crumble into small pieces under friction, and is hence well adapted for stowage. It also emits little smoke, a point of great importance in naval warfare, where the smoke of ordinary coals would reveal the position of vessels to a distant enemy. Its chief locality is the north-west of the South Wales basin and the north of the Tyne and Blyth district.

In addition to the above-named varieties, we must mention the remarkable deposit of Bathgate, near Edinburgh, commonly known as the "Torbane hill mineral or Boghead cannel coal," respecting which a curious lawsuit arose upon the question whether or not the substance was to be considered as "coal." It is of a dull brown colour in the upper part, and black in the lower part of the seam, and of low specific gravity. It contains about 20 per cent. of aluminous ash, which remains after ignition in the form of the original lump, retaining 6 to 10 per cent of carbon. About 70 per cent., therefore, consists of volatile matter, whence the great value of the mineral for two purposes; 1st for gas making; 2nd for distillation, by Young's process, in close vessels at a low temperature, whereby a large number of liquid hydrocarbons of various densities and boiling points are obtained, fit respectively for illuminating and lubricating purposes, together with paraffin and other solid products.

The analyses already given fairly represent the ordinary composition of the several classes of coals.

Valuation of Coal.—A ready method of accurately estimating the general value of coal as fuel is yet a desideratum. Its elementary analysis affords the means of calculating its theoretical heating power; but it is found in practice that the amount of work indicated by this result can never be obtained, and further that the condition of mechanical division, draught of furnaces, and many other extraneous circumstances affect the result so largely, that the actual work obtained seldom bears any palpable relation to the theoretical indication.

The weight of water in pounds raised *one degree* in temperature by the combustion of 1 cubic inch of each of a large number of combustible substances, and also by such a weight of each as combines with 1 cubic inch of oxygen, has been determined by the direct experiments of Lavoisier, Laplace, Despretz, Dulong, Rumford, Regnault, Andrews, and others, the general principle of their methods consisting in the use of an apparatus wherein the entire heat of combustion was absorbed by a known weight of water, the whole arrangement being protected from the influence of external changes of temperature, and the increase of temperature of the water being known by the simultaneous indication of several delicate thermometers suspended in it. (See HEAT.)

The method of Berthier, though only approximative, affords useful indications when applied, with certain precautions, to various samples of the same class of coal or from the same mine.

It is based upon the reduction of oxide of lead by the carbon and hydrogen of the fuel, in fact the combustion of the coal at the expense of the oxygen of litharge, the weight of metal produced indicating the amount of oxygen expended, whence the heating power may be calculated. It is found that 1 pt. of pure carbon produces 34·5 of metallic lead; hence if a sample of fuel produces 25, the heating power is $\frac{25}{34\cdot5}$ of that of carbon, or assuming that 1 lb. of carbon raises 7900 lbs. of water 1°, 1 lb. of the sample of coal is capable of raising 5724 lbs. of water by 1°.

Various tables have been given by Berthier and other experimenters, of results obtained in this manner, the following being some of the most useful figures: —

Coking Dowlais coal	produces	31·8 lbs. lead
Glamorgan	„	31·2 „
Newcastle	„	30·9 „
Wigan cannel	„	28·3 „
Cherry coal, Derbyshire	„	27·2 „
Glasgow cannel	„	24·9 „
Durham	„	31·6 „
Pennsylvanian anthracite	„	30·5 „

By a comparison of the result of any experiment with these standard figures, a tolerably fair estimate may be made of the specific value of any sample.

The method of operating consists simply in mixing a known weight of the finely powdered fuel with about forty times its weight of pure litharge, and exposing the mixture to a gentle heat in a large crucible finally raised to a clear red heat. The pot is removed, struck on the floor to assist the settling of the metal, and broken when cold. The button is cleaned and weighed. The accuracy of the result depends greatly upon the relative proportion of hydrogen and oxygen: when they are in the proportion necessary to form water, the result is tolerably correct; but it is evident that any excess of hydrogen over and above this proportion introduces an error, inasmuch as its heat equivalent is calculated as if it were carbon, while in truth it is about four times as great. The results of the British Admiralty investigation, by De la Beche and Playfair, exhibit a variation often "amounting even to a virtual contradiction" of the simultaneous results of direct combustion.

Other experimenters have found difficulty in obtaining constant results by Berthier's method, but Mitchell has found that the difficulty may be obviated by substituting ordinary carbonate of lead for the litharge.

The best practical method of valuing fuel consists in employing an apparatus similar to those used by Andrews and other chemists in the determination of the actual heating power of carbon, hydrogen, &c., or of a miniature furnace to which a known volume of air is supplied, with arrangements, such as readily suggest themselves, for the complete utilisation of the heat evolved. It is to be remembered that the real value of all such results is simply relative.

The imperfect character of most boiler arrangements and the large quantity of coal which passes into the ash-pit unconsumed, together with the irregular supply of draught and the amount of heat absorbed by the great excess of cold air, result practically in an enormous loss of heating power, to an extent which, even under the most careful management, is widely variable. Thus, the results obtained in the American and British Admiralty experiments exhibit grave discrepancies. In the case of the latter investigation, a Cornish boiler only 12 feet long was employed, and "even from the smallness of the boiler employed, the results fell short by 20 per cent. of the maximum amount of work which the same fuels could perform when applied to larger boilers constructed and set on the same principle. The inquiry is rendered less efficient from another cause, viz. the want of a thorough control and measurement of the air passing through the furnace."

We have referred to the injurious properties of *sulphur* as an ingredient in coals, and to its average quantity in various classes of fuel. Its amount may be estimated by fusing in a large silver capsule a few pieces of caustic potash and ⅓ of its weight of nitrate of potash and a few drops of water. After cooling, the finely powdered coal is added, and the whole re-fused till white. The mass is dissolved in hydrochloric acid, and the sulphuric acid produced is estimated by precipitation with chloride of barium. It is always necessary at the same time to estimate the quantity of sulphuric acid present in the ash of the coal, and to deduct this from the amount obtained as above, in order to obtain the quantity due to the oxidation of the sulphur only.

Deflagration with 2 pts. nitre and 10 of chloride of sodium may also be employed, but the greatest care is necessary to control the action.

The importance, in addition to a knowledge of the chemical character of a fuel, of a consideration of its *mechanical condition*, is amply exhibited by the fact acknowledged in both the government series of experiments, that it was a *sine quâ non* that the toughness of coals must be such, for naval use, as to resist, without crumbling, the constant friction in the ship's hold, at the same time that its fracture must be such that it packs into the smallest possible space. In this respect, coals of equal heating power vary 20 per cent. at least. "This factor, which is of extreme importance in steam-navigation, becomes reduced the more the cleavage of the coal or the shape of the fuel approaches the form of a cube. In order to attain, at least, a relative idea of the waste occasioned by transport, *i. e.* of the attrition of the individual pieces of coal against each other, and conversion of unbroken coal into dust unfit for use, which is occasioned by the motion of the vessel, the various specimens were rotated in a drum for the same length of time, and the dust thus produced separated and weighed."

The subjoined table shows some of the results of the British investigation as regards:

1. Number of lbs. of water at 100° C. converted into steam by 1 lb. of fuel.
2. Ditto, after deducting portions of coke contained in the ash.
3. Theoretical evaporative power in lbs. of water of 100° C. evaporated by 1 lb. of fuel calculated from litharge test.
4. Weight of coal per cubic foot of stowage in lbs.

COAL-GAS. The gas produced by the destructive distillation of pit-coal at regulated temperatures.

The apparatus used in the manufacture of coal-gas on the great scale consists essentially of a system of closed retorts of fireclay or cast-iron, the exit pipes from which communicate with a *hydraulic main*, in which the crude gas deposits part of its tar and ammoniacal products. It passes thence into a series of condensing pipes, wherein it is exposed to the action of a large refrigerating surface, and deposits the greater part of its tar and ammonia-liquor, the last portions being removed in its passage through another series of vessels of various forms and modifications, in which the gas is *scrubbed*, by being obliged to force its way through breese, stones, or other materials which serve to comminute it and bring it into thorough contact with a stream of water which continually percolates the vessel. It is then deprived of its carbonic acid and sulphuretted hydrogen in lime purifiers, and finally is drawn by exhausting apparatus into the gas-holders, passing on its way through the station-meter and other beautiful and delicate apparatus, whereby the pressure and amount of gas which passes into the town are regulated and registered. (See the article COAL-GAS in *Ure's Dictionary of Arts, Manufactures and Mines.*)

The following analysis by Bunsen and Roscoe exhibits the composition of Manchester coal-gas prepared from Cannel coal:

Hydrogen	45·58
Marsh-gas	34·90
Carbonic oxide	6·64
Olefiant gas or ethylene	4·08
Tetrylene	2·38
Sulphuretted hydrogen	0·29
Nitrogen	2·46
Carbonic acid	3·67
	100·00

In addition to these constituents, there are frequently present traces of ammonia, vapour of sulphide of carbon, cyanogen, and oxygen.

The composition above given, represents that of a first-rate sample of gas; but the relative proportion of the several ingredients depends both upon the quality of coal used, upon the temperature of the retorts, and the time during which the distillation is continued. It is to the olefiant gas and other heavy hydrocarbons present in comparatively small quantities, that the illuminating power of gas is chiefly due; the maintenance of a full proportion of this gas is therefore of the utmost importance. The following table shows the quality of gas from 1120 lbs. of common coal at the Clifton gas-works, Manchester, at different periods of distillation:

Hours from commencement.	100 measures purified gas contain			100 measures of purified gas consume
	Olefiant gas.	Nitrogen.	Other inferior gases.	Oxygen.
1	10	0	90	164
3	9	0	91	168
5	6	0	94	132
7	5	15	80	120
9	2	9	89	112
11	0	15	85	90

Hence, two things should especially be avoided in the manufacture of gas, viz. too low a heat and a too long continuation of the distillatory process. The effect of too low a heat is a great diminution of the gaseous products, the chief result of the distillation being the production of tar. The effect of continuing the distillation too long, is that gases of very feeble illuminating power are evolved, together with nitrogen, which, when once mingled with the combustible gas, cannot be removed by any known method, and must seriously impair its illuminating power.

The following table by Hughes gives an idea of the relative and absolute yield of different kinds of coal under practical management:

Name of Coal.	Cubic feet of Gas per ton.	Specific Gravity of Gas.	Weight of Gas in lbs. per ton of Coal.	
Newcastle, average of 3 samp.	11,492	·452	398	Hedley.
„ „ 10 „	11,336	·416	362	Clegg.

Staffordshire, average of 4 samples	10,467	·376	302	Clegg.

Modes of estimating Luminiferous Value.

The gas manufacturer relies much as an indication of the purity of his gas, upon its specific gravity, which he commonly takes approximately by means of a balloon, containing when full 1000 cubic inches, and gauged by a ring which fits its largest diameter when full. Attached to the balloon is a car, into which as many grains are put as balance the balloon. This result, although not scientifically accurate, gives, after correction for temperature, barometer, &c., an indication of sufficient practical value, but of course vitiated by the presence of any large amount of carbonic acid.

The comparison of gases by the photometer is a test preferred by many gas-engineers to all others. It consists of the comparison either of shadows, or of transmitted light passing through a semi-transparent disc of paper with reflected light striking on an opaque portion, in juxtaposition to the transparent portion. When the light is so adjusted that the shadows are precisely similar, or that the light reflected and that transmitted by the disc are equal, then the lights are to each other in the ratio of the squares of their distance from the disc or screen.

The only chemical test upon which the practical gas maker commonly relies, is the amount of absorption which takes place upon introducing into a known volume of gas a bubble of chlorine or a drop of bromine, the principal hydrocarbons to which gas owes its luminiferous value being condensed by these reagents into oily compounds. These methods are, however, of the roughest kind.

An accurate result may, however, be obtained by substituting for chlorine or bromine a fragment of coke saturated with Nordhausen sulphuric acid, the experiment being made over mercury and the absorption being allowed to go on for two or three hours. Subsequently the sulphurous acid produced in this action is removed by a ball of binoxide of manganese, and finally aqueous vapour is removed by a ball of caustic potash. The quantity of carbonic acid being also determined, the difference between the two experiments gives the amount of luminiferous hydrocarbons accurately. The value of these, being in proportion to the carbon they contain, is ascertained by exploding portions of gas before and after removal of the hydrocarbons with excess of oxygen, and comparison of the amount of carbonic acid produced in each case respectively. The difference is the amount due to the carbon of the luminiferous constituents. (For details of the mode of analysis of such a mixture, we refer to *Miller's Chemistry*, ii. 661, to *Regnault's Cours Elémentaire*, iv. 73, to *Clegg's Treatise on Coal-gas*, and more particularly, for the most recent and accurate methods of operation, to *Bunsen's Gasometry*, p. 107, to the article ANALYSIS (VOLUMETRIC) OF GASES, in this Dictionary, and to the article COAL-GAS in the new edition of *Ure's Dictionary of Arts, Manufactures and Mines*.)

The Rev. W. R. Bowditch proposes to determine the relative illuminating power of coal-gas, in other words, the proportion of ethylene, propylene, and other heavy hydrocarbons contained in it, by the intensity of the red colour which they impart to woody fibre moistened with sulphuric acid. When rich coal-gas, giving the light of 20 to 25 sperm candles from consumption of 5 ft. per hour, is slowly passed through clean deal sawdust, well moistened with pure sulphuric acid diluted with five or six volumes of water, so that it may not blacken the sawdust, that substance instantly acquires a beautiful pink colour, which gradually deepens to a dark mahogany; with a poor gas, which gives the light of only ten or twelve candles at the same rate of consumption, the coloration is faint at first and deepens very slowly. The differences of coloration are so considerable and constant that they may perhaps be used as a means of determining the illuminating value of the gas. By using a standard acid, the same kind of sawdust, a uniform volume of gas, and the same sized U-tubes, notation of time and depth of colour would give a close approximation to the light-giving value. (Proc. Roy. Soc. xi. 25.)

In addition to the constituents estimated by these operations, it is frequently important to determine sulphuretted hydrogen and bisulphide of carbon. Their presence is well detected by the simple and useful apparatus of Wright, consisting of an arrangement for condensing the products of combustion from a gas-jet, and testing the condensed liquid for sulphuric acid.

Their *amount* may be determined by passing a known volume of gas through, 1st, a solution of caustic potash in water, and, 2nd, a solution of the same reagent in alcohol. The former absorbs sulphuretted hydrogen; the latter the sulphide of carbon, which it converts into xanthate of potassium, which is in turn decomposed by boiling. Dilute solution of nitrate or acetate of lead being added, sulphide of lead is precipitated, and its amount is judged of by comparison of the shade of colour produced in the liquid with a solution containing a known quantity of lead precipitated in the like form.

Another method of detecting sulphide of carbon in coal-gas, is to pass it through an ethereal solution of *triethylphosphine*, which forms with sulphide of carbon a compound crystallising in splendid ruby-red prisms (Hofmann, Chem. Soc. Qu. J. xiii. 87). This is a much more delicate test than the preceding. Hofmann found that, on passing a current of coal-gas through a solution of four or five drops of triethylphosphine in ether contained in a bulb-apparatus, a distinct red coloration was produced after 0·2 of a cubic foot of gas had passed through the liquid; and after 0·8 of a cubic foot had passed, the whole of the ether had evaporated, and the inner surface of the bulb-apparatus was lined with a beautiful net-work of the ruby crystals.

Lastly, the sulphide of carbon may be easily detected by a method which likewise serves for its removal. For this method we are indebted to the Rev. W. R. Bowditch (*loc. cit.*) It consists in decomposing the sulphide of carbon with hydrogen, thereby converting it into sulphide of hydrogen, which is easily detected and removed by the usual methods. When a mixture of hydrogen and vapour of sulphide of carbon is passed through a tube filled with slaked lime or clay, which has been dried between 400° and 500° Fahr., and is kept between 400° and 600° during the passage of the gaseous mixture, the sulphide of carbon is completely decomposed, the lime or clay is blackened by a deposit of carbon, and sulphur sublimes in the exit-tube, while sulphide of hydrogen passes through, and may be detected by acetate of lead. The same effect is produced when coal-gas containing sulphide of carbon is passed over heated lime or clay, the free hydrogen in the gas then decomposing the sulphide of carbon in the manner just described. This method may be applied on the large scale to the purification of coal-gas from sulphide of carbon, the sulphuretted hydrogen resulting from the decomposition being afterwards removed by slaked lime in the ordinary way. Passing the gas over clay likewise decomposes other volatile sulphur-compounds which are not removed by the ordinary mode of purification with lime. These compounds, including sulphide of carbon, have long been regarded as the most troublesome impurities of coal-gas. The sulphur which is evolved from the coal as sulphuretted hydrogen, is easily removed by slaked lime; indeed, the London coal-gas rarely, if ever, exhibits the slightest trace of this compound. But it always contains sulphide of carbon or some of the other volatile sulphur-compounds just mentioned, the proportion of sulphur contained in it varying, according to Hofmann (*loc. cit.*), from 6·68 to 10·33 grains in 100 cubic feet. Now the sulphur in burning produces sulphurous acid, which, besides being offensive to the senses, is very destructive to art-decorations, bindings of books, &c. The removal of these sulphur-compounds will, therefore, do away with the greatest existing objection to the use of gas in dwelling houses.

The use of clay as a purifier of coal-gas is likewise attended with other advantages, as it absorbs ammonia and other nitrogen-compounds which diminish the light-giving power of the gas. This effect is especially conspicuous when the gas given off towards the end of the distillation (p. 1036), is submitted to the action of the clay.

Clay which has become charged with the impurities from coal-gas, may afterwards be used as a manure.

Secondary Products obtained in the manufacture of Coal-gas.

After a charge of coal has been worked off to the extent considered most desirable, the man-lids are removed from the retorts, and the residual coke raked out into barrows, wheeled away and quenched with a jet of water. Its appearance and uses, as fuel for locomotives, in the blast furnace, and in a vast number of technical operations, are too well known to need description, nor does space allow us to go into details of the numerous processes which have been employed, with more or less success, for the economical preparation and purification of coke.

The liquids condensed during the passage of the gas through the hydraulic mains and condensers, are of a very complex character. They consist essentially of two portions, the one watery and the other tarry, crude coal-tar varying in density between 1120 and 1150, the lightest portions containing the largest proportion of liquid oils.

The basic substances contained in coal-tar include ammonia, aniline, picoline, chinoline, pyridine, toluidine, and others of less importance.

The acids include acetic in minute quantities, rosolic, brunolic, &c., but principally phenic or carbolic acid. The neutral portions contain benzene, toluene, cumene, cymene (liquids); naphthalene, paranaphthalene or anthracene, chrysene, and pyrene (solids).

The commercial distillation of coal-tar is performed in large retorts, holding from 200 to 500 gallons. The first products are gaseous; next passes water charged with ammoniacal salts, and contaminated with black oily matter.

The proportion of oil continues to increase, while that of watery products diminishes. Finally, after from 5 to 10 per cent. of the whole has passed in the form of "light oil," the product becomes heavier than water, and is collected apart as "kreasote oil," or "dead oil" used extensively for the pickling or antiseptic preparation of timber, and for burning into lamp-black. Naphthalene and other solid products now become abundant and the oil becomes pasty. Finally, the residue in the retort is run off while hot, and on cooling becomes hard and brittle, constituting *asphalt*, a product used in the manufacture of coarse varnishes, and on a vastly larger scale in laying down railway and other bridges, as a means of protecting their masonry from the infiltration of water.

The heavy oil contains a variety of hydrocarbons of high boiling point, together with carbolic acid, to which latter it probably owes its antiseptic qualities.

The light oils obtained in the above process are rectified, whereby a further portion of heavy oils is separated and crude *naphtha* obtained. This is agitated with sulphuric acid. and the supernatant liquid, upon careful rectification, yields the "highly rectified naphtha" or "benzole" of commerce, consisting of a complex mixture of at least five oils boiling at from 149° to 392° F., and of specific gravity ·860 to ·890.

The watery liquids deposited in the condenser during the manufacture of gas, are devoted to the production of sulphate and chloride of ammonium. They are usually removed from the gas-works in flats or canal boats of known capacity, under contracts commonly taken at so much per 10,000 gallons.

The manufacture of chloride of ammonium direct from the liquors, is conducted on a large scale in Liverpool, and consists essentially in saturating with hydrochloric acid, concentrating the liquors, crystallising and subsequently subliming the crystals. A far larger portion, however, of the crude gas-liquor is consumed in the manufacture of sulphate of ammonium, by processes which consist essentially of distillation, with addition of lime, to decompose ammoniacal salts, and condensation of the vapour in sulphuric acid, concentration and crystallisation of the solution after saturation has been effected. Sulphate of ammonium is employed in large quantities in the manufacture of artificial manures.

The above are the chief products of distillation of coal at high temperatures, while those at regulated low temperatures are far different. Under the latter conditions, the gaseous products are reduced to their minimum, while the quantity of liquid and solid hydrocarbons is proportionately increased.

The Boghead Cannel of Bathgate, near Edinburgh, is extensively submitted to the process of slow destructive distillation, under the patent of Young, while successful efforts have lately been made by Mr. Blackwell, of Dudley, to turn to account the vast heaps of somewhat bituminiferous shales or "batts" ejected from the coal mines of Staffordshire.

To this subject we cannot further refer than to remark that for practical purposes the products may be separated into three portions.

1. Remains liquid at all ordinary temperatures and forms, after proper purification, a valuable burning oil, known as "photogen."—2. Deposits crystals of solid hydrocarbons at very low temperatures; used extensively for lubricating machinery and known as "paraffin oil."—3. Solid or semi-solid products, which when freed from the oils which contaminate them by pressure, &c. consist chiefly of paraffin (*q. v.*) and may be employed alone or mixed with tallow, stearin, &c. in the manufacture of candles.

W. W.

COBALT. *Kobalt, Cobaltum.—Symbol*, Co. *Atomic Weight*, 29·5.—The use of cobalt for imparting a blue colour to glass, appears to have been known to the Greeks and Romans, though most of their blue glasses were coloured with copper. Some of the pigments used by the ancient Greeks likewise contained cobalt. The use of cobalt for the preparation of smalt was introduced about the middle of the sixteenth century. The metal, in an impure state, was first extracted by Brandt in 1733.

Cobalt is not a very abundant metal. It occurs as an arsenide, called *tin-white cobalt* or *smaltine;* as sulpharsenate, or *cobalt-glance;* as arsenate, or *cobalt-bloom;* as sulphate and as *black earthy cobalt*, which is a compound of protoxide of cobalt with peroxide of manganese. It also occurs in small quantity in other minerals—as in selenide of lead, cerite, and Flemish coal. In the metallic state, it occurs only in meteorites, many of which contain from 0·1 to 1 per cent. of it, associated with iron and nickel.

Preparation.—Cobalt is extracted chiefly from smaltine and cobalt-glance, or from the impure arsenate obtained by roasting these ores. The roasting has the effect of driving off a considerable portion of the arsenic, which escapes as arsenious oxide, and is condensed in the manner described under ARSENIC (i. 365). The roasted product consists essentially of basic arsenite, arsenate and sulphate of cobalt, together with iron, nickel, and in smaller quantity bismuth, tin, copper, and manganese. When prepared on the large scale, it is mixed with twice its weight of siliceous sand, and sent into the market under the name of *zaffre*, which is used for giving a blue colour to glass, enamels, and pottery glaze.

The preparation of a pure oxide of cobalt from the native minerals or the roasted ore, is effected by one of the following processes:

1. Cobalt or smaltine is dissolved in nitric acid, or in dilute sulphuric or hydrochloric acid, to which a little nitric acid is added,—or the roasted ore or earthy cobalt is dissolved in sulphuric or hydrochloric acid alone; the filtered solution is

evaporated nearly to dryness, a large quantity of arsenious acid then separating out; and the liquid is largely diluted, separated from the arsenious acid, and treated with sulphuretted hydrogen as long as the sulphides of arsenic, copper, and bismuth (together with tin) continue to be precipitated. The solution is then filtered, and heated till the excess of sulphuretted hydrogen is expelled and the protoxide of iron converted into sesquioxide; carbonate of sodium is then added in excess, while the liquor is hot, to precipitate the nickel and cobalt in the form of carbonates, and the iron as sesquioxide. The precipitate is then well washed and digested with excess of aqueous oxalic acid; the soluble ferric oxalate is separated by filtration from the oxalates of nickel and cobalt, which are insoluble even in excess of oxalic acid; and the latter salts are triturated with dilute ammonia (it should be strong ammonia according to Stromeyer) and dissolved in excess of the ammonia, by agitation and gentle heating in a close vessel. The filtered solution, after exposure to the air for several days, deposits the oxide of nickel in combination with oxalic acid and a small quantity of ammonia, while pure oxalate of cobalt remains in solution. (The oxalate of nickel separated as above may be freed from the small quantity of cobalt-salt which falls down with it, by washing with water, re-dissolving in ammonia, exposing the liquid to the air, and separating the solution which contains the cobalt from the nickel precipitate, the purity of which increases at each repetition of the process.) The residue obtained by evaporating the ammoniacal solution of the oxalate, yields sesquioxide of cobalt when ignited in the air, and metallic cobalt if ignited out of contact of air. (**Laugier.**)

2. To avoid the tedious passing of sulphuretted hydrogen through the liquid, the arsenic acid may be precipitated by first mixing the dilute solution with a ferric salt, and then adding carbonate of potassium in small successive portions and with constant agitation, as long as the precipitate continues to exhibit a white or brownish colour (arsenate of ferric oxide); till, in short, a filtered sample of the liquid gives a reddish precipitate with a small quantity of carbonate of potassium. If the quantity of ferric oxide be sufficient, and the proportion of carbonate of potassium rightly adjusted, the whole of the arsenic acid and ferric oxide may be precipitated. If the copper and bismuth be then removed by sulphuretted hydrogen, it only remains to separate the nickel from the cobalt. (Berthier.)

3. Finely powdered cobalt-ore is carefully roasted, and 1 pt. of it added in successive small portions to 3 pts. of acid sulphate of potassium heated to the melting point in an earthen or cast-iron crucible. The mass, which is thereby rendered pasty, is then more strongly heated till it fuses quietly and no longer gives off fumes of sulphuric acid, as it is necessary to drive away the excess of that acid. The mass, while yet liquid, is then taken out of the crucible with an iron spoon — broken to pieces after cooling — dissolved in boiling water, and filtered from the arsenates of iron and cobalt, which are not soluble in a neutral liquid. Sulphuretted hydrogen is then passed through the filtrate to throw down any antimony, bismuth, or copper that may be present — the liquid again filtered, and pure carbonate of cobalt precipitated by carbonate of potassium. To prevent the formation of arsenate of cobalt, the roasted cobalt-ore, before fusion with sulphate of potassium, may be mixed with a small quantity of ferrous sulphate, so that the arsenic acid may combine with the oxide of iron contained in that salt in preference to the oxide of cobalt. No nickel is taken up by the liquid, because the sulphate of nickel is decomposed at a red heat [not so, however, the sulphate of nickel and potassium, unless the heat applied is very strong]. The solution retains but a trace of iron at the utmost. (Liebig, Pogg. Ann. xviii, 164.)

4. One part of pulverised smaltine or cobalt-glance is fused in a covered earthen crucible with 3 pts. of carbonate of potassium and 3 pts. of sulphur, whereby the whole of the metals present are converted into sulphides, and sulphide of potassium is formed, which unites with the sulphide of arsenic, forming a soluble sulpharsenate. The heat must be so regulated that the sulphide of cobalt may not fuse, but remain in the form of a crystalline powder, because, if fusion takes place, portions of the sulpharsenate of potassium will be enclosed in the fused mass, and will be difficult to wash out. The mass is then freed from sulpharsenate of potassium by repeated exhaustion with water and decantation; again treated with carbonate of potassium and sulphur, and then with water to remove the rest of the arsenic; afterwards dissolved in nitric acid or in dilute sulphuric acid mixed with nitric; the solution is treated with sulphuretted hydrogen to remove any remaining arsenic, together with bismuth and copper; and the filtered liquid is treated as in method *b*, to separate the cobalt from nickel and iron. (Wöhler, Pogg. Ann. vi. 277.)

5. To obtain cobalt from black earthy cobalt ore, the mineral is dissolved in hydrochloric acid; the arsenic, antimony, lead, and copper are precipitated by sulphuretted hydrogen; the filtrate is boiled with nitric acid to promote the further oxidation of the iron; the iron is precipitated by boiling with acetate of sodium, and the cobalt separated from the filtrate by sulphuretted hydrogen, which leaves acetate of manga-

nese undecomposed. The precipitate is free from nickel, but contains a trace of zinc. The liquid freed from arsenic and copper by sulphuretted hydrogen may likewise be precipitated by sulphide of potassium or barium, and the washed precipitate treated with cold dilute hydrochloric acid, which dissolves the sulphides of manganese, zinc, and iron, and leaves all the sulphide of cobalt undissolved. (Wackenroder, N. Br. Arch. xvi. 133.)

The greatest difficulty in the preparation of pure cobalt-compounds is the separation of the nickel. Laugier's method (*vid. sup.*), affords the means of obtaining a cobalt solution free from nickel; but it leaves a certain portion of the cobalt in the nickel precipitate. For more complete modes of separation, adapted to quantitative analysis, see COBALT, DETECTION AND ESTIMATION OF (p. 1046).

Metallic Cobalt.—Cobalt is reduced from its oxides by ignition with charcoal more easily than iron, or the difficultly fusible brittle metals; when thus reduced, however, it contains carbon. The purest metal is obtained by igniting the oxalate in a covered crucible, the salt, $Co^2C^2O^4$, being then resolved into 2 at. cobalt and 2 at. carbonic anhydride. If the oxalate or the mixture of oxide and charcoal be covered with pounded glass free from reducible metals, and heated in a blast-furnace, the cobalt is obtained in the form of a fused regulus. Cobalt may also be reduced from its oxides by hydrogen; and if the heat applied be not very great, the reduced metal is pyrophoric, like iron reduced under similar circumstances, and takes fire on coming in contact with the air, producing cobaltoso-cobaltic oxide.

Cobalt rendered compact by fusion is rather hard, has a granular fracture, and is somewhat malleable at a red heat. The presence of arsenic, manganese, &c., renders it brittle. It has a steel-grey colour, inclining to red; in the polished state, however, rather to white. The statements respecting its specific gravity vary from 8·513, (Berzelius), to 8·7 (Lampadius). That of the metal reduced by hydrogen was found by Rammelsberg, in five experiments, to vary from 8·132 to 9·495; mean 8·957. Specific heat = 0·10696 (Regnault), 0·1172 (De la Rive and Marcet). It fuses more easily than iron, less easily than gold. It is attracted by the magnet, and is capable of receiving a slight magnetic power when rubbed with a magnet, this power, according to Pouillet, not being destroyed by the strongest red heat. A minute quantity of arsenic destroys the magnetic power.

Cobalt is not altered by the action of air and water at ordinary temperatures, but when very strongly heated, it takes fire, and is converted into cobaltoso-cobaltic oxide, $C^{12}O^7$. It decomposes aqueous vapour at a red heat. It is dissolved by hydracids and by dilute oxygen acids, with evolution of hydrogen, slowly however, and only when heated. The solutions have a fine red colour, and contain salts corresponding in composition to the protoxide. It is easily dissolved by nitric acid, likewise forming a proto-salt.

Cobalt forms several classes of compounds, the most numerous, and generally speaking the best defined being the proto-compounds or cobaltous compounds, *e.g.* CoCl, Co^2O, Co^2S, Co^2SO^4, &c.; there are likewise cobaltic- or sesqui-compounds, *e.g.* Co^4O^3, Co^4S^3; three oxides intermediate between the two preceding; a dioxide, Co^2O^2, a disulphide, Co^2S^2, a tricobaltic phosphide, Co^3P, and several classes of salts containing bases in which cobalt is united with the elements of ammonia.

COBALT, ALLOYS OF. Cobalt unites readily by fusion with antimony and arsenic, the combination being attended with incandescence; the resulting alloys are brittle, and have an iron-grey colour.

Protoarsenide of Cobalt, CoAs, is found native as smaltine or tin-white cobalt, being in fact the most abundant of cobalt ores. It occurs in crystals belonging to the regular system, viz. cubes, octahedrons, dodecahedrons, and intermediate forms. Cleavage octahedral, distinct; cubic, in traces. It occurs also massive and in reticulated and other imitative shapes. Specific gravity 6·3 to 6·6. Hardness 5·5. Lustre metallic. Colour tin-white, inclining sometimes to steel-grey, sometimes to silver-white. It tarnishes by exposure. Streak greyish-black. Brittle. Emits a smell of arsenic when broken. It yields no sublimate when heated in a test-tube; but in a tube open at both ends a sublimate of arsenious acid is formed. It dissolves in nitric acid, leaving a residue of arsenious acid.

Arsenide of cobalt is never found quite pure, the cobalt being always more or less replaced by nickel or iron; those varieties which contain more nickel than cobalt are called *Cloanthite* (see NICKEL). The following are analyses of smaltine containing little or no nickel; *a*, from Riechelsdorf in Hesse, by Stromeyer (Gött. gelehrte Anzeige, 1817, p. 72); *b*, from Tunaberg in Sweden, by Varrentrapp (Pogg. Ann. xlviii. 505); *c*, from Schneeberg in Saxony, by E. Hofmann (*ibid.* xxv. 485); *d*, from the same locality, by v. Kobell; *e*, from Riechelsdorff, by Jäckel (*Rammelsberg's Mineralchemie*, p. 23):—

	As	Co	Fe	Cu	Ni	Bi	S	
a .	74·21	20·31	3·42	0·16	—	—	0·88 =	98·98
b .	69·46	23·44	4·95	—	—	—	0·90 =	98·75
c .	70·37	13·95	11·71	1·39	1·79	0·01	0·66 =	99·88
d .	71·08	9·44	18·48	trace	—	1·00	trace =	99·92
e .	66·02	21·21	11·60	1·90	—	0·04	0·49 =	101·26

The formula CoAs requires 71·8 As and 28·2 Co. When the proportion of iron is considerable, as in *c*, *d*, *e*, the mineral is also called *Safflorite*. The composition of *e* agrees more nearly with the formula $(Co; Fe)^4As^3$. *Chathamite*, from Chatham in Connecticut, is chiefly an arsenide of nickel and iron containing 1·3 per cent. cobalt.

Smaltine occurs altered to cobalt-bloom by oxidation.

Sesquiarsenide of Cobalt. Co^2As^3.—This compound also occurs native as Skutterudite or Modumite (*Tesseralkies*, *Hartkobaltkies*, *Hartkobalt*), at Skutterud, near Modum in Norway. It crystallises in the regular system, exhibiting faces of the cube, octahedron, dodecahedron, and trapezohedron. Cleavage cubic, distinct; dodecahedral in traces. Also massive, granular. Specific gravity 6·74—6·84. Hardness = 6. Lustre bright metallic. Colour between tin-white and pale grey, sometimes iridescent. A crystallised specimen analysed by Wöhler (Pogg. Ann. xliii. 591), gave 79·2 As, 18·5 Co, 1·3 Fe = 99·0, the formula requiring 78·2 per cent. As and 20·8 Co. This mineral heated in a closed tube yields a sublimate of metallic arsenic.

When smaltine is ignited in a retort, part of the arsenic is expelled, and there remains a lower arsenide of cobalt, which is non-magnetic, and fuses before the blowpipe to a brittle metallic globule. In cobalt-blue works, crystallised alloys of cobalt and arsenic are often formed, containing also copper and iron. (Scheerer and Francis, Pogg. Ann. l. 513.)

With $\frac{1}{15}$ of its weight of gold, cobalt forms, according to Hatchett, a dark yellow very brittle compound; even $\frac{1}{65}$ pt. of cobalt is sufficient to render gold brittle.

The alloy of cobalt with iron is very hard and difficult to pulverise.

With mercury, cobalt forms a silver-white amalgam, which is attracted by the magnet.

With platinum, it forms a fusible compound.

When cobalt is fused with silver, two layers are formed, the lower consisting of cobaltiferous silver, the upper of argentiferous cobalt; a small quantity of cobalt renders silver brittle.

With tin, cobalt forms a somewhat ductile alloy of light violet colour.

With zinc, it unites only with great difficulty, also with lead and bismuth, which exhibit with cobalt the same deportment as silver.

COBALT, BROMIDE OF. CoBr.—Cobalt takes up bromine-vapour at a dull red heat, forming a green compound which melts, and at a higher temperature suffers partial decomposition. The compound deliquesces rapidly in the air, forming a red liquid. The same solution is obtained by heating finely divided cobalt with bromine and water. It turns violet-red on evaporation, and leaves a green mass when evaporated to dryness. By evaporating the solution over oil of vitriol, red crystals of the hydrated bromide acid are obtained, which soon effloresce in the dry air of the receiver, but deliquesce when exposed to the air in its ordinary state. (Rammelsberg.)

A solution of the bromide forms, with excess of *ammonia*, a blue precipitate, which turns green on exposure to the air, and a red solution which turns brown in the air, and then sometimes deposits red quadratic tables, perhaps consisting of a compound of Co^2Br^3 with bromide of ammonium. (Rammelsberg.)

Bromide of cobalt absorbs *ammonia-gas*, forming ammonio-bromide of cobalt, $3NH^3.CoBr$, a red powder which gradually turns brown, and is resolved by water into a brown solution, and an insoluble green residue containing bromine. (Rammelsberg.)

COBALT, CHLORIDES OF. The *protochloride*, CoCl, is formed, with vivid incandescence, when pulverulent cobalt is heated in a stream of chlorine-gas; it then sublimes in blue crystalline scales. It is also produced in the wet way by dissolving cobalt or the protoxide in hydrochloric acid, hydrogen being evolved in the former case, or by heating the sesquioxide or cobaltoso-cobaltic oxide (Co^3O^4), with hydrochloric acid, its formation being then attended with evolution of chlorine. The solution is pink, and yields by evaporation non-deliquescent crystals of the same colour, consisting of hydrated chloride of cobalt. But if the pink solution be mixed with strong hydrochloric or sulphuric acid, it turns blue the more readily as it is more concentrated and more strongly heated. The effect appears to be due to the abstraction of the crystallisation-water by the strong acid. According to Proust, such a solution sometimes deposits the blue crystals of the anhydrous chloride. The red colour is restored by dilution with water. By evaporating the solution to dryness, or by heating the hydrated crystals, hydrochloric acid is evolved, and a greenish blue mass is obtained, consisting of an oxychloride (Berzelius), which is decomposed at a higher temperature, yielding a sublimate of anhydrous chloride, and leaving an oxidised compound.

The sublimed chloride forms soft loose crystalline spangles, unctuous to the touch, and of light blue colour. On exposure to the air, it takes up water and becomes rose-red, and is then easily dissolved by water, forming a red solution; but if not previously hydrated in this manner, it is very slowly dissolved by water.

The red solution forms a sympathetic ink. Characters written with it on paper are colourless and invisible or nearly so; but when the paper is warmed by holding it near a fire, the writing becomes visible and appears of a beautiful blue. After a while, as the salt absorbs moisture, the colour disappears, but may be reproduced by the action of heat. If the paper be exposed to too high a temperature, the writing becomes black, and does not afterwards disappear. The addition of a nickel-salt to the solution gives a green instead of a blue colour.

Ammonio-chloride of Cobalt, $2NH^3.CoCl$, obtained by passing ammonia-gas over the heated chloride, is a bulky powder of a pale reddish-white colour. With water it forms a red-brown solution, and leaves a green powder. (H. Rose.)

Sesquichloride of Cobalt, Co^2Cl^3, is a very unstable compound, formed by dissolving hydrated cobaltic oxide in cold hydrochloric acid. A brown solution is thus obtained, which begins to evolve chlorine, and pass into the protochloride, this effect taking place instantly on heating the liquid. The sesquichloride is also formed in small quantity when chlorine is passed through a solution of the protochloride mixed with hydrochloric acid, the liquid then assuming a darker colour.

COBALT, DETECTION AND ESTIMATION OF. 1. *Blowpipe Reactions.*—All compounds of cobalt fused with borax or phosphorus-salt before the blowpipe, either in the inner or the outer flame, impart a splendid blue colour to the bead, affording an extremely delicate test of the presence of the metal. The production of the blue colour in *both* flames distinguishes cobalt from all other metals. If the substance under examination contains a large quantity of manganese or iron, as well as cobalt, the bead formed in the outer flame is violet in the former case, green in the latter. If the glass be then heated in the reducing flame, the manganese colour disappears, and that of iron changes to bottle green, the glass then exhibiting either the pure blue due to cobalt, or the greenish blue of a mixture of cobalt and iron.

Cobalt-salts mixed with carbonate of sodium, are reduced on charcoal to a grey magnetic powder of metallic cobalt.

2. *Reactions in Solution.*—Solutions of proto-salts of cobalt or cobaltous salts have a rose-red colour, excepting when they are very concentrated and contain a free acid, in which case they are blue; dilution with water changes the blue colour to red (p. 1042). The neutral solutions faintly redden litmus. *Sulphydric acid* produces no precipitate in cobalt solutions containing an excess of either of the stronger acids; but in a solution of the acetate, or of any cobalt-salt mixed with acetate of potassium it forms a black precipitate of sulphide of cobalt. *Alkaline sulphides* throw down the same precipitate, insoluble in excess of the reagent.

Potash or *soda* forms in cobaltous solutions a blue precipitate of a basic salt, which is insoluble in excess of the reagent, assumes a green or dirty bluish-grey colour on exposure to the air, from formation of sesquioxide, but if protected from the air, is converted into the hydrated protoxide of a dingy red colour. This last change takes place quickly on heating the liquid, even if the air be not excluded. A solution of protochloride of cobalt containing a little sesquichloride, yields with potash a precipitate which does not change to dingy red, even on boiling, but merely acquires a darker colour.

Ammonia added in small quantity to a cobaltous solution forms a blue precipitate consisting of a basic salt, which, by continued digestion with ammonia out of contact of air, is converted into rose-red hydrated cobaltous oxide, the change being, however, much slower than when a fixed alkali is used as the precipitant. In contact with the air, the precipitate becomes green. If more ammonia be added, it dissolves and forms a brownish-red liquid, which, if exposed to the air, absorbs oxygen, becomes red-brown, and then contains salts of various bases, consisting of the elements of ammonia united with the higher oxides of cobalt (see Cobalt-Bases, Ammoniacal). If the solution contains but a small quantity of ammoniacal salts, which will be the case if the original cobalt solution was neutral, potash produces in it a precipitate of hydrated sesquioxide of cobalt; but if chloride of ammonium be added, or if the original solution contained an excess of acid which has been neutralised by the ammonia, potash produces no precipitate.

Neutral *carbonate of potassium* or *sodium*, forms a rose-coloured precipitate of hydrocarbonate of cobalt, which, when boiled, gives off carbonic acid, and assumes a violet, or, if the alkaline carbonate is in excess, a blue colour. If the precipitate be boiled for some time in contact with the air, its colour changes to green. A solution of *acid carbonate of potassium* forms, in neutral cobaltous solutions, a rose-coloured precipitate, with evolution of carbonic acid, the liquid retaining a reddish colour which it does not lose for a very long time. The precipitate ultimately changes to a mass of small rose-coloured crystals, consisting of a compound of neutral carbonate of cobalt with acid carbonate of potassium. Frequently, also, there is formed a compact precipitate, destitute of crystalline structure, and consisting of a compound of neutral carbonate of cobalt with a very small quantity of cobaltous hydrate.—*Carbonate of ammonium* produces a red precipitate of carbonate of cobalt, soluble in excess of the precipitant and in chloride of ammonium; the solution does not turn brown in contact with the air.

Carbonate of barium does not in general precipitate cobaltous salts at ordinary temperatures; from a solution of the sulphate, however, the greater part of the cobalt is precipitated after a very long time, so that the remaining liquid is nearly colourless. From a solution of the chloride, no precipitation takes place in the cold, but by prolonged boiling, the whole of the cobalt is precipitated.

Oxalic acid produces, after some time, a faintly reddish white precipitate, which gradually increases, the whole of the cobalt being ultimately thrown down as oxalate. The precipitate is soluble in ammonia, less easily in carbonate of ammonium. The rose-coloured ammoniacal solution, when exposed to the air, very slowly deposits the oxalate.

Phosphate of sodium produces in neutral cobaltous solutions, a blue precipitate of cobaltous phosphate, soluble with red colour in excess of the cobalt-solution, deposited again on boiling, and redissolving as the liquid cools.

Cyanide of potassium produces a red-brown precipitate completely soluble in excess. The solution has a grass-green colour, changing, after a while, to pale brown, and yields, with hydrochloric acid, a reddish-white precipitate, soluble in potash. Sulphide of ammonium does not precipitate the cobalt from this solution, even after a long time.

Ferrocyanide of potassium produces a green precipitate of ferrocyanide of cobalt, changing after a while to grey; insoluble in hydrochloric acid. *Ferricyanide* of potassium produces a reddish-brown precipitate, likewise insoluble in hydrochloric acid.

Brown peroxide of lead mixed with the solution of a cobaltous salt, precipitates nearly all the cobalt, after some time, in the form of sesquioxide; the reaction is accelerated by heat.

The non-precipitation by sulphydric acid in presence of free mineral acids, and the reactions with alkalis,—especially the formation of a brownish-red solution with excess of ammonia, from which sulphide of ammonium throws down a black precipitate,—are together sufficient to distinguish cobaltous solutions from all others. The blowpipe reaction will of course be resorted to as a confirmatory test.

Many non-volatile organic substances, such as tartaric acid, prevent the precipitation of cobalt by alkalis, but not by sulphide of ammonium.

Sesqui-salts of cobalt, or cobaltic salts.—The liquid formed by passing chlorine into a solution of a cobaltous salt, or by treating it with chlorate of potassium and hydrochloric acid, till it assumes a brown-red colour and smells strongly of chlorine, exhibits the following reactions:—

Sulphydric acid produces no precipitate, but only a milkiness arising from separation of sulphur, the solution at the same time acquiring the rose-red colour characteristic of cobaltous salts. *Sulphide of ammonium*, after saturation of the free acid by ammonium, produces a black precipitate of sulphide of cobalt. *Potash*, a dark black-brown precipitate of hydrated cobaltic oxide. *Ammonia*, a brownish-red solution, which does not change by contact with the air. *Carbonates of potassium and sodium:* green solution which deposits a small quantity of sesquioxide. *Ferrocyanide of potassium*, a green; and *ferricyanide of potassium*, a brownish-red precipitate. *Oxalic acid* slowly produces a precipitate of cobaltous oxalate.

3. *Quantitative estimation.*—Cobalt is generally precipitated from its solutions by *caustic potash*. The basic salt at first thrown down is converted into hydrate (p. 37) by boiling in the liquid, and then well washed with hot water to free it from alkali, which adheres very obstinately to it. It is then dried and ignited in an atmosphere of hydrogen, by which it is reduced to the metallic state. The reduction is most easily performed by placing the dried precipitate in a platinum or porcelain crucible, through the lid of which passes a tube connected with a hydrogen apparatus. The crucible must be heated to full redness over a lamp; if a lower degree of heat be applied, the reduced cobalt will be pyrophoric, and is sure to oxidise partially during weighing. The stream of hydrogen must be kept up till the crucible is quite cold.

As the precipitate thrown down by potash almost always retains a small quantity of alkali, even after prolonged washing, the reduced metal must, after weighing, be well washed with water, till the liquid which runs away no longer exhibits any alkaline reaction. The metal is then to be dried, again ignited in hydrogen gas, and weighed. The difference between the two weighings seldom exceeds 0·2 per cent. If the cobalt has been precipitated from a solution of the sulphate, the precipitate may retain a small quantity of sulphuric acid: in that case, the reduced metal will contain sulphur, but never more than a mere trace, unless the precipitate has been boiled with the liquid for a very long time.

Alkaline carbonates do not precipitate cobalt so completely as the caustic alkalis.

If the cobalt-solution contains ammoniacal salts, the precipitation is not complete even when a caustic alkali is used, and the liquid well boiled. In that case it is necessary to precipitate by *sulphide of ammonium*, wash the precipitate, dry it on the filter, burn the filter to ashes, then dissolve the sulphide in nitric or nitromuriatic acid, and precipitate with potash as above.

If the solution contains none but easily volatile acids, such as nitric or hydrochloric acid, and no fixed base but cobalt, the precipitation may be dispensed with altogether, the liquid being merely evaporated to dryness in the crucible, and the residue ignited in an atmosphere of hydrogen, in the manner already described.

Lastly, cobalt may be completely precipitated from its neutral solutions by *nitrite of potassium*, in the form of potassio-cobaltic nitrite, or cobalt-yellow (p. 1058). The solution is evaporated to a small bulk, and neutralised by potash if it contains excess of acid. A solution of nitrite of potassium is then added, together with sufficient acetic acid to neutralise any free potash in the nitrite: the whole is left at rest for two days, and the yellow compound which has separated is collected on a filter. The filtered liquid should also be treated with nitrite of potassium and acetic acid, and left at rest for some time, in order to see whether any further precipitate forms. The precipitate is washed with solution of chloride or sulphate of potassium, then dissolved in hydrochloric acid, the liquid being heated till it is quite free from nitrous acid, and exhibits the rose-red colour of a cobaltous salt, and the cobalt is finally precipitated by potash. This mode of precipitation serves to separate cobalt from nickel, zinc, manganese, and many other metals. (A. Stromeyer, Ann. Ch. Pharm. xcvi. 218.)

4. *Separation from other elements.*—The metals of the first group (i. 217), are separated from cobalt by precipitating them with *sulphydric acid*, from solutions acidulated with one of the stronger mineral acids. From the metals of the third group and from the non-metallic elements, cobalt is separated by precipitating it as a sulphide with *sulphide of ammonium* from neutral or alkaline solutions. In applying this method to the separation of cobalt from magnesium, it is necessary to add chloride of ammonium to retain the magnesia in solution, and even then the sulphide of cobalt sometimes carries down with it a small quantity of magnesia. This may, however, be prevented by boiling the whole till the free ammonia present is volatilised, then adding a few drops of sulphide of ammonium, and filtering.

Aluminium is best separated from cobalt by precipitation as insoluble diacetate (i. 13). The solution, if acid, is neutralised with carbonate of sodium, *acetate of sodium* is added, and the liquid boiled for some time. The alumina is then precipitated in a form in which it may be easily filtered and washed. The washing must be performed with a warm weak solution of acetate of sodium, as the precipitate is slowly dissolved by pure water. The whole of the cobalt remains in solution, and the alumina, which may contain soda, is dissolved by hydrochloric acid, and precipitated by sulphide of ammonium (i. 155). (H. Rose.)

Aluminium cannot be separated from cobalt by *solution of potash*, the precipitated oxide of cobalt always carrying some of the alumina with it. A better method is to fuse the mixture of the two bases with solid potash in a silver crucible, and extract the fused mass with water. The oxide of cobalt which then remains may contain a little potash, but it is free from alumina.

Another very good mode of separation is to mix the solution of the two bases with tartaric acid and excess of ammonia,—which will not then precipitate either of them,—and add sulphide of ammonium, which will throw down the cobalt and leave the aluminium in solution. The precipitated sulphide of cobalt is then to be treated with nitric acid, &c., as already explained; the filtrate containing the alumina evaporated to dryness, and the residue ignited to burn away the organic matter. If no other base is present, the ignited residue will consist of pure alumina, which may be weighed; in the contrary case, the residue must be dissolved in hydrochloric acid, and the alumina precipitated by one of the methods given on page 155, vol. i. As the burning away of the organic matter takes a long time, it is perhaps better to destroy it by boiling the liquid with chlorate of potassium and hydrochloric acid, and then precipitate the alumina.

Cobalt may also be separated from aluminium by precipitation with *nitrite of potassium*.

From **glucinum**, cobalt may be separated by either of the two methods last-mentioned; also from **yttrium**, **zirconium**, **thorium**, **cerium**, **lanthanum** and **didymium**. The last three metals may also be separated from cobalt by precipitation with *sulphate of potassium* (i. 833), or with oxalic acid from a solution containing excess of ammonia.

From **iron**, cobalt is most easily separated by precipitating the two metals with *sulphide of ammonium*, and digesting the washed precipitate in dilute hydrochloric acid, which dissolves the iron and leaves the cobalt. As, however, very small quantities of sulphide of cobalt may likewise be dissolved, it is best to reprecipitate the iron by sulphide of ammonium, and treat the precipitate with very dilute hydrochloric acid: any slight traces of cobalt that may be mixed with the iron will then be left undissolved.

Cobalt may also be separated from iron (in the state of sesquioxide) in the same manner as aluminium, viz. by boiling the neutralised solution with *acetate of sodium*. The iron is then precipitated, while the cobalt remains in solution. The iron precipitate is washed with warm dilute acetate of sodium, dissolved in hydrochloric acid, and the iron reprecipitated by ammonia; and the cobalt is precipitated by sulphide of ammonium. If the iron in the original solution is in the state of protoxide, it must first be converted into sesquioxide by heating with nitric acid. This method yields very exact results.

A third method of separating iron (as sesquioxide) from cobalt, is to mix the solution, if neutral, with a considerable quantity of chloride of ammonium, then cautiously add ammonia till a permanent precipitate of ferric oxide just begins to form, and precipitate the rest of the iron with *succinate of ammonium*. The cobalt remains in solution, and the ferric succinate, after being washed and dried, is ignited with good access of air, to prevent reduction of iron by the organic matter (see IRON). This method is not, however, so good as the two preceding, as the oxide of iron, when examined by the blowpipe, always exhibits the presence of a small quantity of cobalt.

Lastly, cobalt may be separated from iron by precipitation with *nitrite of potassium*.

From **manganese** (existing in solution as a manganous salt) cobalt may be easily separated by precipitating the two metals as sulphides, and dissolving out the sulphide of manganese with dilute hydrochloric acid, in the same way as for iron.

Another method, proposed by Liebig, is to precipitate the two metals as cyanides with *cyanide of potassium*, then add a sufficient excess of that reagent to redissolve the cyanide of cobalt and part of the cyanide of manganese. The latter is collected on a filter and washed; the filtered liquid is heated, and hydrochloric acid is slowly added by drops, care being taken not to add enough to render the liquid acid; and the separation of the cobalt and manganese is effected exactly in the manner which will be presently described for the separation of cobalt and nickel. The cyanide of manganese previously separated by filtration is dissolved in hydrochloric acid; the solution is boiled till the hydrocyanic acid is completely volatilised, the manganese is precipitated by carbonate of sodium, and the quantity thus obtained is added to that determined the other way.

If the cobalt and manganese exist in solution as chlorides, the liquid may be evaporated to dryness (being transferred to a porcelain crucible when reduced to a small bulk), and the residual chlorides ignited in an atmosphere of *hydrogen* in the manner described at p. 1043, as long as vapours of hydrochloric acid continue to escape. The cobalt is then reduced to the metallic state, while the chloride of manganese remains undecomposed, and may be dissolved out by water. The metallic cobalt which remains is washed with hot water, then digested with a small quantity of very dilute acetic acid, to dissolve out any small quantity of chloride of manganese that may remain, afterwards ignited in a current of hydrogen, and weighed. The manganese is precipitated from the solution of its chloride by carbonate of sodium. If the temperature be raised too high during the reduction by hydrogen, a small quantity of chloride of manganese may be volatilised.

Another mode of separating cobalt from manganese, is to digest the mixed protoxides (precipitated by an alkali) in a solution of *pentasulphide of calcium*, which converts them both into sulphides, dissolving the sulphide of cobalt, and leaving the sulphide of manganese undissolved.

From **nickel**, as from most other metals of the second group, cobalt is most easily separated by precipitation with *nitrite of potassium*, the process being performed exactly as described at p. 1045. With due attention to the precautions there indicated, the whole of the cobalt is precipitated, without a trace of nickel.

Another method is that of H. Rose, depending on the fact that protoxide of cobalt in solution is converted by *chlorine* into sesquioxide, whereas with nickel this change does not take place. The metals or their oxides being dissolved in excess of hydrochloric acid, the solution is diluted with a large quantity of water, about a pound of water to a gramme of the metals or their oxides. Chlorine gas is then passed through the solution for several hours, till, in fact, the space above the liquid becomes permanently filled with the gas; carbonate of barium is then added in excess; and the whole is left to stand for twelve or eighteen hours, and shaken up from time to time. The precipitate, consisting of sesquioxide of cobalt and carbonate of barium, is then collected on a filter, and washed with cold water. The filtered liquid, which has a pure green colour, contains all the nickel without a trace of cobalt. The precipitate is boiled with hydrochloric acid to convert the sesquioxide of cobalt into protoxide, and dissolve it together with the baryta; the latter is then precipitated by sulphuric acid, and the cobalt from the filtrate by potash. The nickel is also precipitated by potash, after the removal of any baryta that the solution may contain by sulphuric acid. This method, if properly executed, gives very exact results. The chief precautions to be attended to, are to add a large excess of chlorine, and not to filter too soon, because the precipitation of sesquioxide of cobalt by carbonate of barium takes a long time.

According to Henry, *bromine* may be used in the preceding process instead of chlorine as the oxidising agent.

Liebig has given several methods of separating these two metals, founded on the difference of their reactions with *cyanide of potassium*. 1. The oxides of the two metals are treated with hydrocyanic acid and then with potash, and the liquid warmed till the whole is dissolved (pure cyanide of potassium, free from cyanate, may also be used as the solvent). The reddish-yellow solution is boiled to expel free hydrocyanic acid, whereupon the cobaltocyanide of potassium ($KCoCy^2$), formed in the cold, is converted into cobalticyanide ($K^3Co^2Cy^6$), while the nickel remains in the form of cyanide of nickel and potassium ($KNiCy^2$). Pure and finely-divided red oxide of mercury is then added to the solution while yet warm, whereby the whole of the nickel is precipitated, partly as oxide, partly as cyanide, the mercury taking its place in the solution. The precipitate contains all the nickel, together with excess of mercuric oxide; after washing and ignition, it yields pure oxide of nickel. The filtered solution contains all the cobalt in the form of cobalticyanide of potassium. It is supersaturated with acetic acid, boiled with sulphate of copper, which precipitates the cobalt in the form of cobalticyanide of copper ($2Cu^3Co^2Cy^6.7H^2O$), and the precipitate retained in the liquid at a boiling-heat till it has lost its glutinous character. It is then washed, dried, ignited, and dissolved in hydrochloric acid mixed with a little nitric acid; the copper is precipitated by sulphydric acid; and the filtrate, after boiling for a minute to expel the excess of that gas, is mixed with boiling caustic potash to precipitate the cobalt (Ann. Ch. Pharm. lxv. 244).—2. Instead of adding the oxide of mercury, the solution containing the mixed cyanides may, after cooling, be supersaturated with chlorine, the precipitate of cyanide of nickel thereby produced being continually redissolved by caustic potash or soda. The chlorine produces no change in the cobalticyanide of potassium, but decomposes the nickel-compound, the whole of the nickel being ultimately precipitated in the form of black sesquioxide. (Ann. Ch. Pharm. lxxxvii. 128.)

Liebig's first method (*ibid.* xli. 291), which consisted in treating the solution of the mixed cyanides with excess of hydrochloric or sulphuric acid, whereby the nickel was precipitated as cobalticyanide of nickel, leaving a solution of cobalticyanide of potassium, has been found, both by himself and others, not to give perfectly satisfactory results. The method by oxalic acid (p. 1040), and the precipitation of nickel from an ammoniacal solution of the two metals by potash (see NICKEL) are not sufficiently accurate for quantitative analysis.

F. Claudet separates cobalt from nickel and other metals in the form of the ammonio-compound described on page 1052, that compound being very insoluble, while corresponding compounds of the other metals do not appear to be formed under the same circumstances.

From **uranium**, in the state of sesquioxide, cobalt, as protoxide, may be separated by means of carbonate of barium, which throws down the uranic oxide and leaves the cobalt in solution. (For other modes of separation, see URANIUM.)

From **zinc**, cobalt may also be easily separated by precipitation with *nitrite of potassium*. Another mode of separation is: Convert the two metals into chlorides, and reduce the chloride of cobalt with hydrogen, as described for the separation of cobalt from manganese; the chloride of zinc then remains unaltered, and may be dissolved out. Thirdly, the metals may be precipitated by carbonate of sodium, the carbonates dissolved in a large excess of acetic acid, and sulphydric acid gas passed through the solution. The zinc is thereby precipitated as sulphide, while the cobalt remains dissolved. To ensure complete separation, it is necessary to add a large excess of acetic acid. Fourthly, the separation may be effected by precipitating the cobalt as sesquioxide, by means of peroxide of lead (p. 1044).

5. *Valuation of Cobalt-ores.*—The value of a cobalt-ore is estimated either by the amount of protoxide that it will yield, or by its power of imparting a blue colour to glass and enamel. (For the latter mode of valuation we refer to the article SMALT.)

To estimate the quantity of protoxide contained in a cobalt ore, the ore may be treated by either of the methods already given (pp. 1039, 1040), to separate the arsenic, copper, iron, &c., the cobalt being afterwards separated from the nickel, and estimated by either of the processes described on pp. 1044, 1045.

(For Plattner's method of estimation in the dry way, see his *Treatise on the Blowpipe*, translated by Muspratt, also *Kerl's Hüttenkünde*, iii. [1] 340, 342).

6. *Atomic Weight of Cobalt.*—Dumas has determined the atomic weight of cobalt by the quantity of silver required to decompose a known weight of the chloride. Pure metallic cobalt was dissolved in nitro-muriatic acid, the solution evaporated to dryness, keeping the hydrochloric acid continually in excess; the residue ignited in a stream of hydrochloric acid gas, or else heated in vacuo; and the chloride of cobalt thus obtained was decomposed by nitrate of silver. Five experiments thus made gave for the atomic weight of cobalt numbers varying from 29·50 to 29·59. Dumas regards 29·5 as the correct number (Ann. Ch. Pharm. cxiii. 24). This agrees with the original determination of Rothof (Pogg. Ann. viii. 185), which was made by converting a known weight of the protoxide into chloride, and then precipitating by nitrate of silver. Schneider (Pogg. Ann. ci. 317), from the analysis of the oxalate, estimated the atomic weight of cobalt at 30; but the number 29·5 is generally regarded as correct.

COBALT, EARTHY, or *Asbolan.*—A variety of wad or earthy manganese, containing oxide of cobalt. (See MANGANESE, OXIDES OF, and WAD.)

COBALT, FLUORIDE OF, CoF, may be obtained by dissolving cobaltous oxide or carbonate in aqueous hydrofluoric acid. The solution yields by evaporation small irregular rose-coloured crystals containing $CoF.H^2O$. The compound dissolves without decomposition in water containing free hydrofluoric acid, or in a small quantity of pure water; but with a larger quantity of water, it is resolved into an acid liquid containing cobalt, and an insoluble pale red basic salt consisting of $2Co^4F^2O.H^2O$. or $2\,(CoO.CoF) + HO$.

Fluoride of cobalt unites with the fluorides of ammonium and potassium, forming sparingly soluble double salts which crystallise in pale red granular crystals. (Berzelius.)

COBALT, IODIDE OF, CoI, is produced by digesting finely divided metallic cobalt with iodine and water, the mixture becoming heated to the boiling point. With a small quantity of water, it forms a green, and with a larger quantity, a red solution, and remains, on evaporation, as a dark green deliquescent mass soluble in alcohol. (Erdmann, J. pr. Chem. vii. 354.)

Ammonio-iodides of Cobalt.—Iodide of cobalt absorbs 3 at. ammonia-gas, forming the compound, $CoI.2NH^3$, which is a reddish-yellow powder. A concentrated solution of iodide of cobalt forms with ammonia a reddish-white precipitate which dissolves on heating, leaving only a few green flocks. The solution deposits small rose-coloured crystals, which, as well as the reddish-white precipitate, consist of $CoI.2NH^3$, but appear also to contain water. When dried, they give off ammonia, turn brown and afterwards green. Water decomposes them, liberating ammonia and depositing a green powder. A dilute solution of iodide of cobalt forms with ammonia a blue precipitate which turns green when exposed to the air, and a brown solution. (Rammelsberg, Pogg. Ann. xlviii. 155.)

COBALT, OXIDES OF. The following oxides of cobalt are known:

Protoxide or cobaltous oxide	Co^2O or CoO
Sesquioxide or cobaltic oxide	Co^4O^3 or Co^2O^3
Intermediate oxides	Co^6O^4 or Co^3O^4 $Co^{12}O^7$ or Co^6O^7 $Co^{16}O^9$ or Co^8O^9

The protoxide is a strong, the sesquioxide a weak base. According to Frémy, the oxide Co^6O^4 is also a salifiable base, which unites directly with acetic acid and exists in some of the ammoniacal salts of cobalt. Frémy has also obtained salts of this nature containing a dioxide of cobalt, Co^2O^2.

Protoxide of Cobalt or *Cobaltous Oxide*, Co^2O.—This oxide is obtained by igniting cobaltous hydrate or carbonate in close vessels; by igniting the protochloride in a stream of aqueous vapour (Schwarzenberg); also, mixed in various proportions with sesquioxide, when finely divided cobalt burns in the air, or when the compact metal is heated to redness in the air. The pure protoxide is a light greenish-grey or olive-green non-magnetic powder. It is reduced to the metallic state at a red heat by hydrogen, charcoal, carbonic oxide, potassium, and sodium. When heated with sulphur, it is converted into sulphide of cobalt and sulphurous anhydride; and with sulphydric acid, it yields water and sulphide of cobalt.

Hydrated cobaltous oxide, or Cobaltous hydrate, CoHO, or *CoO.HO*, is produced when a cobaltous salt is decomposed by potash out of contact of air. A blue basic salt is first produced which changes gradually at ordinary temperatures, quickly, on boiling, into the rose-coloured hydrate. If the cobalt-solution be dropped into strong boiling potash-ley, the change from blue to red is almost too rapid to be traced. Cobaltous hydrate is a powder of a dingy rose-red colour, which gives off water at 100° C., and is converted into the protoxide if the air be excluded, into a higher oxide if exposed to the air. It dissolves readily in acids, forming the cobaltous salts.

Sesquioxide of Cobalt, Cobaltic Oxide, Co^4O^3, is formed when chlorine is transmitted through water in which the hydrated protoxide is suspended, or when a salt of the protoxide is precipitated by a solution of chloride of lime. In the former case, water is decomposed by the chlorine, and hydrochloric acid produced, while the oxygen of the water peroxidises the cobalt:

$$2Co^2O + H^2O + Cl^2 = Co^4O^3 + 2HCl.$$

The sesquioxide of cobalt is precipitated as a black hydrate, which, when cautiously heated to 600° or 700° C., yields the black anhydrous oxide. When sesquioxide of cobalt is digested in hydrochloric acid, chlorine is evolved, and the protochloride formed. Exposed to a low red heat, the sesquioxide loses oxygen, and the compound oxide, $Co^2O.Co^4O^3$, is produced (Hess). When protoxide of cobalt is calcined with a borax glass, at a moderate heat, it absorbs oxygen, and a black mass is obtained, which, mixed with manganic oxide, serves as a black colour in enamel painting.

Sesquioxide of cobalt acts as a weak base. Phosphoric, sulphuric, nitric, and hydrochloric acids dissolve its hydrate in the cold, without decomposition at first, but the resulting salts are afterwards reduced to salts of the protoxide. A protosalt of cobalt containing a small quantity of a sesquisalt is somewhat deepened in colour. The most permanent of the sesquisalts is the acetate; the hydrated sesquioxide while yet moist dissolves in acetic acid, slowly but completely. The solution, which has an intense brown colour, forms a brown precipitate with *alkalis* and *alkaline carbonates*. With *ferrocyanide of potassium*, it forms a dark precipitate, which, if the precipitant is in excess, gives up cyanogen to it, converting it into ferricyanide of potassium and being itself converted into green ferrocyanide of cobalt. Alkaline *oxalates* colour the solution yellow, forming an oxalate of the oxide Co^3O^2, or Co^6O^4.

Cobaltoso-cobaltic oxides.—*a.* The oxide, Co^3O^2 or $Co^6O^4 = Co^2O.Co^4O^3$, is obtained in the free state by heating the nitrate or oxalate of cobalt, or the hydrated sesquioxide, to redness in contact with the air (Hess, Rammelsberg); but according to Beetz and Winkelblech, the oxide thus obtained is $Co^{12}O^7$. When the residue obtained by gently igniting the oxalate in contact with the air is digested in strong boiling hydrochloric acid, the oxide Co^3O^2 remains in hard, brittle, greyish-black microscopic octahedrons having a metallic lustre. The same crystalline compound is obtained by strongly igniting dry protochloride of cobalt, alone or mixed with sal-ammoniac, in dry air or oxygen gas. (Schwarzenberg.)

This oxide, according to Frémy, is also a salifiable base. The corresponding oxalate has already been mentioned. The acetate is obtained by digesting in dilute acetic acid the hydrated oxide obtained by continued action of oxygen on the blue precipitate thrown down from ordinary cobalt-salts by potash not in excess. Frémy also states that when chlorine is passed into the solution of ordinary acetate of cobalt, a brownish-yellow salt is formed containing the base $Co^6Cl^2O^3$, or Co^6O^4 in which 1 at. O is replaced by Cl^2. This chlorine-base exists also in some of the ammonio-compounds of cobalt (p. 45).

b. The oxide, $Co^{12}O^7 = 3Co^2O.Co^4O^3$, is said by Winkelblech to be formed by keeping the hydrated protoxide at a red heat in the air for a considerable time, or by first reducing it to the metallic state by heating it very gently in a stream of hydrogen, and then burning it again by passing air through the tube. According to Rammelsberg, however (Pogg. Ann. lxxiii. 93), the oxide obtained by either of these processes is Co^3O^4.

c. Another oxide, $Co^{16}O^9 = 6Co^2O.Co^4O^3$, is said to be obtained by precipitating cobaltic nitrate with ammonia, exposing the liquid to the air till the blue precipitate turns green, then suspending the precipitate in water, and exposing it to the air for a month till it turns quite yellow. But the yellow hydrate thus formed always retains a trace of nitric acid, which cannot be removed even by long contact with water.

A *cobaltic acid* (or anhydride), Co^6O^5, is obtained in combination with potash, by strongly igniting the oxide, Co^3O^2, or the protoxide or carbonate, with pure hydrate of potassium. A crystalline salt is then formed which, when dried at 100° C., contains $K^2O.3Co^6O^5 + 3aq.$, and gives off 1 at. water at 130°. (Schwarzenberg.)

Dioxide of Cobalt, CoO, or Co^2O^2, has not been obtained in the free state, but may be supposed to exist in the oxycobaltic-salts (p. 1056).

COBALT, OXYSULPHIDE OF, Co^4SO, or *CoS.CoO.*—Produced by igniting the sulphate in hydrogen gas. Water and sulphurous acid escape, and there remains a dark grey sintered mass which is not altered by the further action of the hydrogen. Cold hydrochloric acid decomposes it, dissolving oxide of cobalt and leaving sulphide; but if heat be applied, the sulphide likewise dissolves. (Arfvedson.)

COBALT, OXYGEN-SALTS OF.—The cobaltous salts are produced by dissolving metallic cobalt in the stronger acids; by the action of acids on the protoxide, hydrate, or carbonate; by boiling the hydrate or carbonate in solutions of ammonia-salts, ammonia being then evolved and a cobaltous solution formed; and by precipitation. The carbonate, phosphate, borate, silicate, and those which contain metallic acids, are insoluble in water; most of the others are soluble. The insoluble salts have a violet or peach-blossom colour; the dissolved salts a rose colour. The neutral solutions redden litmus slightly. For their reactions and those of the cobaltic salts, see pp. 1043, 1044.

COBALT, PHOSPHIDES OF.—The *tricobaltic phosphide*, or *tricobalt-phosphine*, Co^6P, was obtained by H. Rose as a grey powder, on passing hydrogen gas over basic phosphate of cobalt ignited in a porcelain tube. It is also produced by the action of phosphoretted hydrogen on chloride of cobalt.

Another phosphide containing a very large excess of cobalt is produced when pieces of phosphorus are thrown on red-hot cobalt; when 1 pt. of the metal is ignited with 7 pts. glacial phosphoric acid and $\frac{1}{16}$ charcoal powder; and when a mixture of 70 pts. metallic cobalt or oxide of cobalt, 100 bone-ash, 50 pounded quartz, and 10 charcoal is exposed for an hour to the heat of a blast-furnace. The compound prepared by the first or second method is bluish-white, with metallic lustre, brittle, of acicular structure, more fusible than cobalt, contains 6 per cent. phosphorus, and burns to a dark blue glass when heated (Pelletier). The product obtained by the third process is of a shining white colour, very fusible, non-magnetic, and often has needle-shaped crystals in its cavities.

COBALT, RED. Syn. with COBALT-BLOOM (p. 1057).

COBALT, SELENIDE OF. Heated cobalt unites with selenium, forming a grey mass, which exhibits metallic lustre and crystalline structure, and melts at a red heat; the combination is attended with ignition. (Berzelius.)

COBALT, SULPHIDES OF. The *protosulphide*, Co^2S, or *CoS*, occurs native as Syepoorite, a massive mineral of steel-grey colour inclining to yellow, found disseminated in grains or veins in ancient schists, associated with magnetic pyrites, at Syepoor, near Rajpootanah, in North-west India. It is employed by the Indian jewellers to give a rose-colour to gold. According to Middleton's analysis Phil. Mag. [3] xxxviii. 352), it contains 35·36 S, and 64·64 Co, agreeing closely with the formula Co^2S.

The protosulphide may be prepared by throwing sulphur on red-hot cobalt contained in a retort, also by heating the protoxide with sulphur, and by igniting cobaltous sulphate to whiteness in a crucible lined with charcoal. As thus obtained, it is a grey laminar mass having the metallic lustre; according to Berthier, it is magnetic. In the wet way, it is produced by precipitating cobaltous acetate with sulphydric acid or any neutral cobaltous solution with an alkaline sulphide. The precipitate is a black powder which gives off water when heated, and in the moist state slowly oxidises in the air, being converted into sulphate. It is insoluble in alkalis and alkaline sulphides, soluble in concentrated mineral acids, insoluble or nearly so in dilute acids. It unites with acid sulphides, forming sulphur-salts, which are all insoluble in water. According to Anthon, it decomposes the solutions of other metals, *e. g.* iron, nickel, copper, and silver, a sulphide of the other metal being precipitated and the cobalt taking its place in the solution. This appears somewhat inconsistent with the action of dilute hydrochloric acid on a mixture of the sulphides of iron and cobalt, which, according to H. Rose (p. 1044), affords a method of completely separating cobalt from iron. It unites with peroxide of cobalt, forming an oxysulphide (*vid. sup.*).

Sesquisulphide of Cobalt, or *Cobaltous Sulphide*, is obtained by precipitating cobaltic acetate with sulphydric acid, or by heating cobaltic hydrate, but not to redness, in an atmosphere of the same gas. It has a dark grey colour. According to Fellenberg (Pogg. Ann. l. 73), it is obtained in graphitic laminæ by igniting the protoxide with sulphur and an alkali. *Linnæite* or *cobalt-pyrites* is commonly stated to be a sesquisulphide, but its composition approaches more nearly to that of the following compound:

Cobaltoso-cobaltic Sulphide, Co^3S^2, or $Co^2S.Co^4S^3$, or $Co^3S^4 = CoS.Co^2S^3$.—*Linnæite* from Müsen, near Siegren, in Prussia, has nearly this composition, yielding, according to Wernekink's analysis, 43·25 S, 53·35 Co, 0·97 Cu, and 2·30 Fe = 98·87, the formula requiring 42 S and 58 Co (Dana, ii. 66). In most varieties of this mineral, however, the cobalt is replaced to a greater extent by copper or nickel. (See LINNÆITE.)

Oxysulphide of cobalt heated in sulphydric acid gas yields a product which appears to be a sulphide intermediate in composition between the proto- and sesqui-sulphides. (Anthon.)

Disulphide of Cobalt, CoS, or CoS^2, may be supposed to exist in combination with arsenide of cobalt in cobaltine (*q. v.*)

COBALT-BASES, AMMONIACAL. (F. Claudet [1857], Phil. Mag. [4] ii. 253.—Genth, Ann. Ch. Pharm. lxxx. 275.—Frémy, Ann. Ch. Phys. [3] xxxv. 257.—Rogojski, *ibid.* xli. 445.—Gregory, Ann. Ch. Pharm. lxxxvii. 125.—Gibbs and Genth, Smithsonian Contributions, 1856; Sill. Am. J. [2] xxxiii. 234, 319; xxxiv. 96; Ann. Ch. Pharm. civ. 150, 295; Jahresber, f. Chem. 1857, 227.—Künzel, J. pr. Chem. lxxii. 209).—Cobaltous salts treated with ammonia in a vessel protected from the air unite with the ammonia, forming compounds which may be called ammonio-cobaltous salts. Most of them contain 3 at. ammonia to 1 at. of the cobalt-salt; thus the chloride contains $CoCl.3NH^3 + \frac{1}{2}aq.$; the nitrate $CoNO^3.3NH^3 + aq.$ They are generally crystallisable and of a rose-colour, soluble without decomposition in ammonia, but decomposed by water, with formation of a basic salt (Frémy). H. Rose, by treating dry chloride of cobalt with ammonia-gas, obtained the compound $CoCl.2NH^3$, and in like manner an ammonio-sulphate has been formed containing $Co^2SO^4.6NH^3$.

When an ammoniacal solution of cobalt is exposed to the air, oxygen is absorbed, the liquid turns brown (p. 37), and new salts are formed containing a higher oxide of cobalt (either Co^4O^5 or Co^2O^3), and therefore designated generally as peroxidised ammonio-cobalt salts. Several of them containing different bases are often formed at the same time.

Most of the peroxidised ammonio-cobalt salts are composed of sesquisalts of cobalt (cobaltic salts), united with 2 or more molecules of ammonia. The composition of the neutral salts may be illustrated by the chlorides, as in the following table:

Diammonio-cobaltic chloride	$Co^2Cl^3.\ 2NH^3$
Triammonio-cobaltic chloride	$Co^2Cl^3.\ 3NH^3$
Tetrammonio-cobaltic chloride	$Co^2Cl^3.\ 4NH^3$
Pentammonio-cobaltic chloride	$Co^2Cl^3.\ 5NH^3$
Hexammonio-cobaltic chloride	$Co^2Cl^3.\ 6NH^3$

The formulæ of the corresponding neutral nitrates are deduced from the preceding by substituting NO^3 for Cl; for the sulphates, oxalates, and other dibasic salts, the number of atoms of cobalt and ammonia must of course be doubled. Thus, *pentammonio-cobaltic sulphate* = $Co^4(SO^4)^3.10NH^3$. There are also several acid and basic salts of the same ammonio-molecules, the formulæ of which will be given further on. Further, there is a class of salts containing the elements of nitric oxide in addition to ammonia, *e. g. pentammonio-nitroso-cobaltic oxychloride* = $Co^4Cl^4O.10NH^3.2NO$. Lastly, Frémy has obtained ammoniacal compounds (oxycobaltic salts) containing salts of cobalt corresponding to the dioxide Co^2O^2.

DIAMMONIO-COBALTIC SALTS.—The sulphite of this group is obtained by adding acid sulphite of ammonium to an aqueous solution of pentammonio-cobaltic chloride containing a very small quantity of ammonia, till the odour of sulphurous acid becomes distinctly perceptible; on leaving the solution to stand for some time, the sulphite separates in brown, nearly insoluble octahedrons, containing $Co^4(SO^3)^3.4NH^3 + 5aq.$ (Künzel.)

TRIAMMONIO-COBALTIC SALTS.—When a solution of pentammonio-cobaltic chloride containing a little ammonia, is mixed with so much acid sulphite of ammonium that the liquid does not smell either of ammonia or of sulphurous acid, it changes colour from red to deep yellow, and deposits *triammonio-cobaltic sulphite*, $Co^4(SO^3)^3.6NH^3 + aq.$, as a yellow powder or in crystalline needles, according to the temperature and concentration of the liquid. It is insoluble in cold water, and is slowly decomposed by boiling with water. Its formation is expressed by the equation:

$$2(Co^2Cl^3.5NH^3) + 2NH^3 + H^2O + 6(NH^4.H.SO^3) =$$
$$[Co^4(SO^3)^3.6NH^3 + H^2O] + 6NH^4Cl + 3[(NH^4)^2.SO^3]. \quad \text{(Künzel.)}$$

TETRAMMONIO-COBALTIC SALTS. Frémy's *Fusco-cobaltic salts.*—These salts are formed when an ammoniacal solution of a cobaltous salt is exposed to the air, and by the action of water on oxy-cobaltic salts. They are brown, and mostly uncrystallisable, but may be obtained in the solid state by precipitation with alcohol or excess of ammonia. They are slowly decomposed by boiling with water, but quickly on addition of an alkali, with evolution of ammonia and precipitation of cobaltic hydrate. They are basic salts, the *nitrate* containing $Co^4O^3.2N^2O^5.8NH^3 + H^2O$, or $\left.\begin{matrix}(NO^2)^2\\(Co^2)'''.H\end{matrix}\right\}O^3.4NH^3$, and the *hyposulphate* $Co^4O^3.2S^2O^5.8NH^3$.

Pentammonio-cobaltic Salts. (Frémy, *loc. cit.*; Gibbs and Genth, *loc. cit.*)—These salts may be divided into two groups, the *Roseo-cobaltic salts*, which have a red colour, varying from brick to rose-red, and the *Purpureo-cobaltic salts*, which are purple, or violet-red. The salts of both groups contain 5 at. NH^3 to 2 at. cobalt, but the roseo-cobaltic salts are, for the most part, neutral, while the purpureo-cobaltic salts are either basic or acid; in some cases, however, as with the chlorides, the difference consists merely in the presence or absence of water, the purple salts being anhydrous, and the red hydrated.

The pentammonio-cobaltic salts are produced by the direct oxidation of ammoniacal solutions of cobaltous salts, as when these solutions are exposed to the air, the red and purple salts being often produced together, the latter especially when the temperature is rather high, and the solution contains a free ammoniacal salt. The purpureo-cobaltic salts are likewise formed by the action of acids on xantho-cobaltic salts (p. 1054).

Pentammonio-cobaltic salts are nearly insoluble in cold water, but soluble in warm water slightly acidulated; the purple salts are in general less soluble than the red. Their taste is purely saline, not metallic. When heated in the dry state, they decompose, giving off ammonia, and yielding an ammonium-salt and a cobaltous salt. Their aqueous solutions, when not acidulated, are decomposed by boiling, giving off ammonia and depositing a hydrated cobaltoso-cobaltic oxide. The solutions of roseo-cobaltic salts boiled with strong acids, are converted into purpureo-cobaltic salts.

Chlorides. 1. *Hydrated Pentammonio-cobaltic chloride*, or *Roseo-cobaltic chloride*, $Co^2Cl^3.5NH^3 + aq.$—This salt was discovered by Claudet and by Genth, in 1851, being the first ammonio-cobaltic salt obtained; the formulæ originally assigned to it, however, gave a somewhat different view of its constitution. It is the most frequent product of the oxidation of an ammoniacal solution of protochloride of cobalt by exposure to the air, the liquid assuming first a brown, and then a red colour, and often, especially if the ammonia and the chloride of cobalt are impure, depositing a small quantity of cobaltic hydrate. The presence of sal-ammoniac in the solution does not facilitate its formation. The reddened solution mixed with strong hydrochloric acid, and carefully guarded against rise of temperature, deposits roseo-cobaltic chloride as a brick-red precipitate, which, after washing with strong hydrochloric acid, then with ice-cold water, and drying at the lowest possible temperature, contains $Co^2Cl^3.5NH^3 + H^2O$. It dissolves in water either cold or warm, with dark-red colour, which, however, changes after a while, especially if the solution be acidulated with hydrochloric acid and heated, to violet-red. The pure aqueous solution when boiled gives off ammonia and deposits hydrated cobaltoso-cobaltic oxide, $Co^3O^4 + xH^2O$.

Roseo-cobaltic chloride forms double salts with the chlorides of the more electronegative metals.

Purpureo-cobaltic chloride, $Co^2Cl^3.5NH^3$.—It has already been mentioned, that the red solution of roseo-cobaltic chloride changes to violet when heated with hydrochloric acid. The same change takes place slowly in the dry salt. This purple modification is often formed, together with the red one and sometimes alone, during the oxidation of ammonio-cobaltous chloride, especially if the temperature is rather high, and the solution contains sal-ammoniac. By boiling the oxidised liquid with excess of hydrochloric acid, and crystallising the precipitated carmine-coloured powder from water acidulated with the same acid, the purpureo-cobaltic chloride is obtained pure. It may also be prepared by boiling a xantho-cobaltic salt (p. 1054),—the nitrate being best adapted for the purpose—with hydrochloric acid; lastly, by boiling any other purpureo-cobaltic salt with hydrochloric acid. It forms small violet-red or purple crystals, which, according to Dana, are dimetric combinations, $P \,.\, \infty P\infty \,.\, P\infty$. Length of principal axis = 1·9016. $P : P$ in the lateral edges = 114° 8′; in the terminal edges, 107° 12′. Specific gravity 1·802. The crystals are anhydrous, nearly insoluble in cold water, soluble without decomposition in boiling water slightly acidulated with hydrochloric acid. A larger addition of hydrochloric acid, or a solution of an alkaline chloride, precipitates it slowly in the cold, quickly on boiling. The solution yields with *dichloride of platinum* a brown-red precipitate, composed of flat microscopic needles, containing $Co^2Cl^3.5NH^3.2PtCl^2$.

Cyanides.—*Roseo-cobaltic cobalticyanide*, $(Co^2Cy^3.5NH^3).Co^2Cy^3 + \frac{3}{2}H^2O$, is precipitated by cobalticyanide of potassium from roseo-cobaltic solutions, in cherry-coloured crystals apparently having the form of rhombic prisms, insoluble in cold water, decomposed by hot water. The *ferricyanide*, $(Co^2Cy^3.5NH^3).Fe^2Cy^3 + \frac{3}{2}H^2O$, is an orange-coloured crystalline precipitate, possessing similar properties.

Oxides.—*Roseo-cobaltic oxide* is obtained in solution by decomposing the solution of the chloride with oxide of silver, or better—since chloride of silver is somewhat soluble in roseo-cobaltic chloride—by decomposing the sulphate with baryta-water.

The solution has an alkaline taste and reaction, absorbs carbonic acid from the air, and decomposes with facility.—*Purpureo-cobaltic oxide*, obtained in like manner, forms a violet-red alkaline solution, which absorbs carbonic acid from the air, and suffers decomposition when concentrated.

Nitrates.—The *neutral* or *roseo-cobaltic nitrate*, is obtained, as a shining yellow precipitate, when an ammoniacal solution of cobaltous nitrate is left to oxidise in the air, (crystals of Frémy's oxycobaltic nitrate are frequently also formed at first, but subsequently disappear). The deep wine-red liquid yields, by spontaneous evaporation, red crystals, containing $Co^2(NO^3)^3.5NH^3. + H^2O$, easily soluble even in cold water. According to Dana, they are monoclinic combinations $\infty P\infty . [\infty P\infty] . + P\infty . - P\infty . \infty P$. Inclination of faces, $\infty P : \infty P$ in the clinodiagonal principal section = 103°; $\infty P\infty : P\infty = 140° 30'$; $\infty P\infty : -P\infty = 136°$. From the solution of these crystals, or from the original oxidised ammoniacal solution, nitric acid added in the cold throws down a brick-red precipitate of the hydrated salt; but on boiling the liquid with nitric acid, the *anhydrous nitrate*, $Co^2(NO^3)^3.5NH^3$, is thrown down as a violet-red crystalline precipitate. It dissolves in dilute ammonia and separates from the solution by spontaneous evaporation in dimetric crystals $P . P\infty . \infty P . \infty P\infty . 3P3$. Inclination of $P : P$ in the lateral edges, = 82° 40′. This anhydrous salt is nearly insoluble in cold water, more soluble in hot water, but the solution is easily decomposed by heat; addition of nitric acid prevents the decomposition. The anhydrous salt explodes when heated, giving off nitrous vapours, and leaving black sesquioxide of cobalt.—A *basic nitrate*, probably $Co^4O^3.2N^2O^5.10NH^3 + 7H^2O$ or $\left.\begin{matrix}(NO^2)^2 \\ (Co^2)'''.H\end{matrix}\right\}O^3.5NH^3 + 3H^2O$, is obtained in purple scaly crystals, when a solution of the hydrated neutral nitrate, mixed with a large quantity of nitrate of ammonium and a little free ammonia is left to evaporate. These crystals are decomposed by solution in water, and when boiled with hydrochloric acid, yield with brisk effervescence, a purple-red solution and a deposit of purpureo-cobaltic chloride (Gibbs and Genth). Both this basic nitrate and the anhydrous neutral nitrate appear to belong to the so-called purpureo-cobaltic group. Künzel, by exposing an ammoniacal solution of cobaltous nitrate to the air till it had acquired a dark olive-brown colour, and then adding nitrate of ammonium, obtained a yellow crystalline precipitate, to which he assigns the formula $2(Co^4O^3.10NH^3).5N^2O^5$.

Oxalates.—*Roseo-cobaltic oxalate* is precipitated by oxalate of ammonium from a solution of the chloride immediately, from the nitrate very slowly; it may be purified by recrystallisation from water containing ammonia. The cherry-coloured crystals, which are rhombic prisms of 101° 48′, with a brachydome of 108° 54′, contain $\left.\begin{matrix}(C^2O^2)''^3 \\ (Co^4)^{vi}\end{matrix}\right\}O^6.10NH^3 + 6aq.$; they are nearly insoluble in pure water. The *basic*, or *purpureo-cobaltic oxalate*, $\left.\begin{matrix}(C''O^2)^2 \\ (Co^4)^{vi}\end{matrix}\right\}O^5.5NH^3 + 3aq.$, separates in violet-red needles on adding oxalate of ammonium to a solution of purpureo-cobaltic chloride.

Oxalo-sulphates.—An *acid oxalo-sulphate*, $Co^4O^3.2C^2O^3.2SO^3.10NH^3 + 3H^2O$ or $\left.\begin{matrix}(C^2O^2)'' \\ (SO^2)'' \\ (Co^2)'''H\end{matrix}\right\}O^4.5NH^3 + H^2O$, is obtained in brick-red, ill-defined needles by boiling roseo-cobaltic sulphate for several hours with excess of oxalic acid. The solution of this salt assumes a violet-red colour on addition of ammonia, and, if exactly neutralised, yields by evaporation prismatic crystals of a *basic oxalo-sulphate*, $\left.\begin{matrix}(C^2O^2)'' \\ (SO^2)'' \\ (Co^4)^{vi}\end{matrix}\right\}O^5.10NH^3 + 7H^2O$, which is more soluble than the acid salt, and is easily decomposed by boiling.

Sulphates.—*Roseo-cobaltic sulphate* is generally (but not always) produced in an ammoniacal solution of cobaltous sulphate by atmospheric oxidation, the liquid becoming first brown and then dark red. On carefully adding sulphuric acid to this red solution, the sulphate is deposited as a brick-red crystalline powder, which may be purified by washing with cold water and recrystallisation from a slightly acidulated solution. The cherry-coloured crystals, containing $\left.\begin{matrix}(\overset{''}{SO^2})^3 \\ (Co^4)^{vi}\end{matrix}\right\}O^6.10NH^3 + 5H^2O$, are, according to Dana, dimetric combinations, $P . 2P . P\infty . 0P . \infty P . \infty P\infty$. Inclination of $P : P$ in the terminal edges = 107° 20′. Length of principal axis = 1·0866. The salt is nearly insoluble in cold water, sparingly soluble in boiling water, and crystallises from the solution on cooling. It dissolves in dilute ammonia, and crystallises unaltered from the purple-red solution. On boiling the neutral salt, a dark brown powder separates, which, after drying in the air, contains $Co^2O^3 + 3H^2O$, while luteo-cobaltic sulphate remains in solution, being, however, partially decomposed.

An *acid (purpureo-cobaltic) sulphate*, $Co^4O^3.4SO^3.10NH^3 + 5H^2O$, or $\left.\begin{matrix}(S''O^2)^2\\(Co^2)'''H\end{matrix}\right\}O^4.5NH^3 + 2H^2O$, is obtained by mixing the anhydrous chloride (p. 46) with oil of vitriol to a thick pulp, diluting the solution with twice its bulk of water, as soon as the evolution of hydrochloric acid has ceased, then washing the violet-red needles which separate with a little cold water, and pressing them; also by adding oil of vitriol to roseo-cobaltic sulphate till an oily liquid is produced; digesting this for an hour or two, taking care to avoid escape of oxygen, diluting the evolved purple solution with an equal bulk of water, and recrystallising. The crystals are red prisms; according to Dana, rhombic hemihedral combinations, $\infty P . \infty\breve{P}\infty . \frac{1}{2}\breve{P}\infty . \frac{\breve{P}2}{2} . \infty\breve{P}2$. Inclination of $\infty P : \infty P = 106°$; $\frac{1}{2}\breve{P}\infty : \frac{1}{2}\breve{P}\infty$, on the principal axis $= 122° 42'$. The salt has an acid taste and reaction, dissolves easily in water, but is quickly converted into the neutral (roseo-cobaltic) sulphate; especially by slow evaporation of a solution prepared with the aid of heat. (Gibbs and Genth.)

Sulphite. $\left.\begin{matrix}(\overset{\prime\prime}{SO})^2\\(Co^4)^{vi}\end{matrix}\right\}O^6.5NH^3 + \frac{2}{3}H^2O$.—Black-brown, heavy, amorphous precipitate, formed when sulphurous acid gas is passed through a dilute ammoniacal solution of pentammonio-cobaltic chloride; also by passing the gas through water in which tri-ammonio-cobaltic sulphite (p. 1051) is suspended. It is insoluble in cold water, and is decomposed by boiling water. (Künzel.)

NITROSO-PENTAMMONIO-COBALTIC, or XANTHO-COBALTIC SALTS. (Gibbs and Genth, *loc. cit.*)—These salts are produced by passing the nitrous vapours evolved from a mixture of nitric acid and starch or sawdust, into ammoniacal solutions of cobaltous salts, or into neutral, acid, or ammoniacal solutions of roseo- or purpureo-cobaltic salts. The gas is absorbed; fumes of carbonate of ammonia make their appearance; the liquid gradually assumes a dark reddish-brown colour, and then, on cooling, generally deposits a xantho-cobaltic salt.

Xantho-cobaltic salts are brownish-yellow, more soluble in water than the roseo- or purpureo-cobaltic salts, the dilute solutions having a yellow, the more concentrated solutions a dark brown colour. They decompose, though not easily, when these solutions are boiled sometimes also below the boiling temperature—giving off ammonia and depositing a dark-coloured heavy powder. The addition of a few drops of acetic acid prevents this decomposition; but, on adding a small quantity of an inorganic acid, nitric oxide gas is evolved, and a purpureo-cobaltic salt is formed, which, however, is difficult to separate from the undecomposed xantho-cobaltic salt.

The xantho-cobaltic salts appear to have the composition of sesquisalts of cobalt, associated with 5 or 10 at. NH^3, 1 or 2 at. NO, and 1 or 2 at. water.

The *chloride*, or rather *oxychloride*, $Co^4OCl^4.10NH^3.2NO + H^2O$, or $\left.\begin{matrix}(Cl^2O)''\\(Co^2)'''H\end{matrix}\right\}5NH^3.NO$, is not produced by either of the reactions just mentioned, but may be prepared by decomposing the sulphate with chloride of barium, and evaporating the filtrate at a gentle heat, after adding a few drops of acetic acid. It forms brownish-yellow, iridescent crystals. Its solution, mixed with *trichloride of gold*, yields a double salt, which, by recrystallisation from hot water, is obtained in brownish-yellow, iridescent prisms, containing $Co^4OCl^4.10NH^3.2NO.2AuCl^3 + 2H^2O$.—The *chloroplatinate*, $Co^4OCl^4.10NH^3.2NO.4PtCl^2 + 2H^2O$, is nearly insoluble in water, but may be crystallised from hot dilute hydrochloric acid. The *chloromercurate*, $Co^4OCl^4.10NH^3.2NO.8HgCl + 2H^2O$, is obtained by precipitation in pale brownish-yellow laminæ; by recrystallisation from hot slightly acidulated water, in brownish-yellow needles.

Xantho-cobaltic ferrocyanide, $Co^4OCy^4.10NH^3.2NO.2FeCy + 7H^2O$, is obtained by precipitating the nitrate with ferrocyanide of potassium (the solutions of the chloride and sulphate are merely clouded by that reagent) in orange-yellow prismatic crystals, which give up their water easily and without decomposition, are insoluble in cold water, and are decomposed by hot water.

The *nitrate*, which is a basic salt, containing $Co^4O^3.2N^2O^5.10NH^3.2NO + H^2O$, or $\left.\begin{matrix}(NO^2)^2\\(Co^2)'''H\end{matrix}\right\}O^3.5NH^3.NO$, forms light brownish-yellow quadratic prisms, having P : P in the lateral edges, between 100° 45′ and 101° 15′.

The *oxalate*, $Co^4O^3.2C^2O^3.10NH^3.2NO + 5H^2O = \left.\begin{matrix}(C^2O^2)''\\(Co^2)'''H\end{matrix}\right\}O^3.5NH^3.NO + 2H^2O$, is obtained by precipitation in yellow acuminated crystals, insoluble in cold, sparingly soluble in boiling water, decomposed by boiling.

The *sulphate*, $Co^4O^3.2SO^3.10NH^3.2NO + H^2O$ or, $\left.\begin{matrix}(SO^2)''\\(Co^2)'''H\end{matrix}\right\}O^3.5NH^3.NO$, crystallises in thin plates, apparently rhombic. It dissolves in strong sulphuric acid, giving off but little nitric oxide, and forming a red oily liquid, which gives off nitric oxide abundantly on addition of water, while the remaining liquid consists chiefly of ammonio-cobaltous sulphate, usually mixed with a small quantity of acid purpureo-cobaltic sulphate.

HEXAMMONIO-COBALTIC, or LUTEO-COBALTIC SALTS. (Frémy; Gibbs and Genth, *loc. cit.*)—These salts, discovered by Frémy, are often produced by the direct oxidation of ammonio-cobaltous solutions; frequently also by the decomposition of pentammonio-cobaltic salts, although their molecule contains an additional atom of ammonia. They are of yellow or brownish-yellow colour, more soluble in water than the roseo-cobaltic salts, and yield brownish-yellow solutions. They are very permanent in presence of acids, but are decomposed by continued heating with sulphuric acid; in neutral or alkaline solutions they are easily decomposed by boiling.

Luteo-cobaltic chloride, $Co^2Cl^3.6NH^3$, is often formed during the oxidation, by exposure to the air, of an ammoniacal solution of protochloride of cobalt mixed with a large quantity of coarsely-pounded sal-ammoniac (in other cases, the products are roseo and purpureo-cobaltic chloride); almost always, if the ammoniacal solution contains sulphate of cobalt as well as chloride: in the latter case, a salt is formed containing sulphuric and hydrochloric acids, and this, when boiled with hydrochloric acid and chloride of barium, yields a solution of luteo-cobaltic chloride. This salt, purified by repeated crystallisation, forms brownish orange-coloured crystals of specific gravity 1·7016. They belong to the trimetric system, and, according to Dana, exhibit the faces $\infty P \,.\, 0P \,.\, \bar{P}\infty \,.\, 3\breve{P}\infty$, two faces, $\infty\breve{P}3$, on one side only of the macrodiagonal, and four faces, $\frac{4}{3}P$, lying in one zone. Inclination of $\infty P : \infty P = 113° 16'$. It dissolves easily in boiling water, and separates for the most part as the solution cools. It is precipitated unaltered by hydrochloric acid and the chlorides of the alkali-metals. Boiling aqueous ammonia decomposes it slowly, with formation of chloride of ammonium and a dark brown oxide of cobalt.

Concentrated solutions of luteo-cobaltic chloride and dichloride of platinum, yield orange-coloured needles of a chloroplatinate containing $Co^2Cl^3.3PtCl^2.6NH^3 + 3$ aq.; dilute solutions deposit yellow needles of the same compound with $10\frac{1}{2}$ at. water; these, according to Dana, are monoclinic combinations $\infty P \,.\, \infty P\infty \,.\, 0P$. Inclination of $\infty P : \infty P$, in the clinodiagonal section, $= 107° 10'$; $0P : \infty P\infty = 114° 15'$. The crystals are often twins united by the face 0P.—*Trichloride of gold* forms with luteo-cobaltic chloride a yellow precipitate, consisting of small granular crystals, $Co^2Cl^3.AuCl^3.6NH^3$.

Luteo-cobaltic iodide, $Co^2I^3.6NH^3$, is thrown down by iodide of potassium from luteo-cobaltic solutions, as a yellow precipitate, nearly insoluble in cold water, moderately soluble in hot water, and separating in brownish-yellow crystals on evaporation. The bromide is obtained in like manner as a deep yellow precipitate, in other respects resembling the iodide.

Luteo-cobaltic cobalticyanide $(Co^2Cy^3)^2.6NH^3 + \frac{1}{3}H^2O$, is precipitated by cobalticyanide of potassium as a yellowish flesh-coloured precipitate composed of microscopic, oblique rhombic crystals. *Ferricyanide of potassium* forms an orange-yellow precipitate, exhibiting the same forms under the microscope.

Luteo-cobaltic oxide.—By decomposing the sulphate with baryta-water, a brownish-yellow alkaline solution is formed, which absorbs carbonic acid from the air, and is decomposed by evaporation, with evolution of ammonia and deposition of a black powder.

Luteo-cobaltic nitrate, $Co^2(NO^3)^3.6NH^3$, separates from an oxidised solution of ammonio-cobaltous nitrate in orange-coloured crystalline laminæ, the supernatant liquor being usually red and containing roseo-cobaltic nitrate. The salt, purified by recrystallisation, forms crystals belonging to the dimetric system, with the faces $P \,.\, 3P \,.\, 0P$. Angle of $P : P$ in the lateral edges $= 110° 20'$; of $3P : 3P$ in the same $= 153° 52'$. Length of principal axis for $P = 1·0161$.

Carbonates.—The *neutral carbonate*, probably $Co^4(CO^3)^3.12NH^3 + 7H^2O$, is obtained by decomposing a solution of the chloride with carbonate of silver, and leaving the liquid to evaporate, in rhombic crystals, $\infty P \,.\, \infty\breve{P}\infty \,.\, \breve{P}\infty$ Inclination of $\infty P : \infty P = 116° 50'$; $\breve{P}\infty : \breve{P}\infty$ on the principal axis $= 114° 16'$. If the air has had access to the solution, the crystals are generally mixed with those of the acid salt. The *acid carbonate*, $(Co^2)'''HC^2O^6.6NH^3 + \frac{5}{2}$aq., separates, on passing carbonic acid gas into the solution of the neutral salt, in large brown-red crystals, which, according to Dana, are monoclinic combinations, as $P \,.\, \infty P\infty \,.\, [\infty P\infty] \,.\, 0P \,.\, -P \,.\, +2P\infty$. Inclination of

$\infty P : \infty P$, in the clinodiagonal section, = 85° 54′; $0P : \infty P$ = 102° 20′; $0P : \infty P\infty$ = 71° 44′; $0P : -P$ = 139° 50′; $\infty P : +2P\infty$ = 111° 46′.

Oxalates.—The *neutral oxalate* is thrown down by oxalate of ammonia, as a reddish-yellow precipitate composed of slender needles, insoluble in water, easily soluble in oxalic acid, and separating therefrom in wine-yellow, efflorescent, prismatic crystals, containing $Co^4(C^2O^4)^3.12NH^3 + 4H^2O$. The *acid oxalate* was not obtained.

Luteo-cobaltic sulphate is obtained, mixed with the chloride, when an ammoniacal solution of cobaltous sulphate and chloride mixed with a large excess of coarsely pulverised sal-ammoniac, is left exposed to the air. The crystalline mass deposited at the bottom of the vessel is dissolved in hot water; the filtrate is acidulated with a few drops of sulphuric acid and treated with sulphate of silver; and the liquid, after filtration and concentration, is left to crystallise. The salt is also (though not constantly) produced by the action of strong ammonia on roseo-cobaltic sulphate, the change consisting simply in the assumption of 1 at. NH^3: also as a product of the decomposition of roseo-cobaltic sulphate (a salt of another base, not yet further examined, called by Genth and Gibbs *praseo-cobalt*, being sometimes formed simultaneously). The wine-yellow crystals of luteo-cobaltic sulphate contain $Co^4(SO^4)^3.12NH^3 + 5H^2O$, and give off 4 at. water in dry air, or in vacuo. According to Dana, they are trimetric combinations, $\infty P . 0P . \frac{3}{4}P . \frac{2}{3}P . 3\bar{P}\infty . \breve{P}\infty$; also with $3P\infty$ or $\infty\breve{P}\frac{3}{2} . \bar{P}\infty . 3\breve{P}\infty$; also with $0P$ and $\breve{P}\infty$. Inclination of $\infty P : \infty P$ = 113° 38′ and 66° 22′; $\infty\breve{P}\frac{3}{2} : \infty\breve{P}\frac{3}{2}$ = 88° 44′ and 91° 16′; $P\infty ; \breve{P}\infty$, on the principal axis = 112° 8′; $P\infty : \breve{P}\infty$, also on the same = 88° 22′; Luteo-cobaltic sulphate is isomorphous with the chloride, and the two salts are capable of crystallising together in all proportions.

Luteo-cobaltic chromate, obtained by precipitation (pure only from the nitrate), is yellow, soluble in hot water, and separates therefrom in yellow crystals. This salt also crystallises in all proportions with the chloride. (Gibbs and Genth.)

AMMONIO-PERCOBALTIC SALTS, or OXYCOBALTIC SALTS. **Frémy** (*loc. cit.*).—These salts contain 5 at. ammonia associated with a basic salt of dioxide of cobalt. Thus, the *nitrate* is $Co^2O^2.N^2O^5.5NH^3. + H^2O$, and the *sulphate*, $Co^2O^2.SO^3.5NH^3 + \frac{3}{2}H^2O$. They are produced by the action of the air on concentrated solutions of ammonio-cobaltous salts. They have generally an olive-brown colour; crystallise well, are but slightly soluble in the ammoniacal liquid, and are decomposed by water, especially when hot, with evolution of oxygen, liberation of ammonia, and separation of a green basic salt containing the oxide Co^3O^4. The nitrate of this group was first prepared, though not analysed, by L. Gmelin. (*Handbook*, v. 342.)

The oxycobaltic salts may be supposed to contain the diatomic base, Co^2O, thus:

$$\text{The } \textit{nitrate} = \left.\begin{matrix}(NO^2)^2\\(Co^2O)''\end{matrix}\right\}O^2.5NH^3.$$

$$\text{The } \textit{sulphate} = \left.\begin{matrix}(SO^2)''\\(Co^2O)''\end{matrix}\right\}O^2.5NH^3.$$

General formulæ of the Ammoniacal Cobalt-compounds.—These compounds may be represented as ammonium-salts, in which part of the hydrogen in one or more molecules of NH^4 is replaced by ammonium itself, and another portion, in the ammonio-cobaltous salts, by the monatomic radicle Co' = 29·5; in the ammonio-cobaltic salts by the triatomic radicle Cco''' = Co^2 = 59; and in the ammonio-percobaltic salts, by the diatomic radicle $(CcoO)''$ = 75. Such formulæ have been proposed by Weltzien (Ann. Ch. Pharm. xcvii. 19), and H. Schiff (Compt. rend. liii. 411).

In the following formulæ, which are nearly the same as those of Schiff, the symbol Am stands for NH^4 and X for a monatomic acid radicle, such as nitryl, NO^2.

α. Diammonio-cobaltous salts . . . . . = $\left.\begin{matrix}N(Co'AmH^2)\\X\end{matrix}\right\}O$

β. Triammonio-cobaltous salts . . . . . = $\left.\begin{matrix}N(Co'Am^2H)\\X\end{matrix}\right\}O$

γ. Pentammonio-percobaltic salts (oxycobaltic salts) = $\left.\begin{matrix}N^2[(CcoO)''Am^3H^3]\\X^2\end{matrix}\right\}O^2$

δ. Tetrammonio-cobaltic salts (fusco-cobaltic salts) = $\left.\begin{matrix}N^3(Cco'''AmH^8)\\X^2H\end{matrix}\right\}O^3$

ε. Pentammonio-cobaltic salts:

Diacid, or Purpureo-cobaltic . . . $\left.\begin{matrix}N^3(Cco'''Am^2H^7)\\X^2H\end{matrix}\right\}O^3$

Triacid, or Roseo-cobaltic . . . . $\left.\begin{matrix}N^3(Cco'''Am^2H^7)\\X^3\end{matrix}\right\}O^3$

ζ. Xantho-cobaltic salts . . . . . . = $\left.\begin{matrix}N^3[Cco'''Am^2H^6(NO)]\\X^2H\end{matrix}\right\}O^3$

η. Hexammonio-cobaltic salts (luteo-cobaltic salts) = $\left.\begin{matrix}N^3(Cco'''Am^3H^6)\\X^3\end{matrix}\right\}O^3$

Some of these formulæ, viz. those of the fusco-, purpureo-, and xantho-cobaltic salts, differ by 1 at. H from those previously given; but in compounds of such complexity, the question of 1 atom of hydrogen more or less can scarcely be decided by analysis.

The formulæ of the chlorides and oxychlorides are deduced from those in the table by substituting 1 or more at. Cl for a corresponding number of atoms of XO.

The salts β are transformed, by the joint action of ammonia and oxygen into γ, and these, by further oxidation, are resolved into ammonia and the salts δ, which again, by addition of 1 at. NH^3 are transformed into ϵ; and these last, by the further action of ammonia, yield η. The salts ζ are formed by the action of nitrous acid on ϵ, and are reconverted into the diacid salts ϵ, with evolution of nitric oxide, by the action of strong acids.

For Weltzien's formulæ, see *Graham's Elements of Chemistry*, 2nd edition, ii. 721. Gibbs and Genth object to the representation of these compounds as ammonium-salts, and express their composition by means of formulæ involving so-called conjugate radicles, such as $6NH^3\frown Co^2$ in the luteo-cobaltic salts, and $NO\frown 5NH^3\frown Co^2$ in the xantho-cobaltic salts. It is not easy to say what is gained by such a mode of representation.

COBALT-BLOOM. *Erythrine, Prismatic Red Cobalt, Red Cobalt-Ochre, Cobalt-mica, Kobalt-blüthe.*—A hydrated arsenate of cobalt, $Co^3AsO^4 + 4H^2O$, or $3CoO.AsO^5 + 8HO$, occurring in monoclinic crystals, in which the orthodiagonal, clinodiagonal, and principal axis are as 1·3818 : 1 : 0·9747. Inclination of clinodiagonal to principal axis = 70° 54′; $\infty P : \infty P = 111° 16'$. Observed faces $+ P\infty \,.\, + P \,.\, [\infty P \infty] \,.\, [\infty P 4] \,.\, \infty P\frac{3}{2} \,.\, \infty P \infty$ sometimes with $+ 3P\infty$ and $+ \frac{3}{2}P\infty$ between $\infty P \infty$ and $+ P\infty$. The faces $\infty P \infty$ and $+ P\infty$ are vertically striated. It is likewise found in globular and vermiform masses; also pulverulent, incrusting. Specific gravity = 2·948. Hardness, 1·5—2·5, least on $[\infty P \infty]$. Lustre on $[\infty P \infty]$ pearly; on the other faces, adamantine inclining to vitreous. Colour, red of various shades, grey and green; the red tints incline to blue when viewed at right angles to cleavage. Streak, peach-blossom red. Sectile. Flexible in thin plates.

Analyses of cobalt-bloom from Schneeberg by Karsten (Pogg. Ann. lx. 261), gave

As^2O^5	Co^2O	Fe^2O	Ca^2O	H^2O	
38·43	36·52	1·01	—	24·10	= 100·06
38·30	33·42	4·01	—	24·08	= 99·81
38·10	29·19	—	8·00	23·90	= 99·19

The formula requires 38·43 As^2O^5, 37·53 Co^2O, and 24·02 water.

The mineral, when heated in a tube, yields water and turns blue if pure, green if it contains nickel or iron. Before the blowpipe, on charcoal, it gives an arsenical odour and melts in the inner flame to a dark grey bead of arsenical cobalt; gives with fluxes the usual cobalt reaction. Dissolves easily in acids.

Earthy cobalt-bloom (*Kobalt-beschlag*), of peach-blossom colour, is arsenate of cobalt with free arsenious acid. A specimen from Schneeberg analysed by Karsten gave 51·00 per cent. As^2O^3, 19·10 As^2O^5, 16·60 Co^2O, 2·10 Fe^2O, and 11·90 water (= 100·70), with traces of nickel, lime, and sulphuric acid.

Cobalt-bloom occurs in minute crystals at Schneeberg in Saxony, Saalfeld in Thuringia, Riechelsdorf in Hessia, Wolfach and Wittichen in Baden, and Modum in Norway. The earthy varieties are found in Dauphiny, in Cornwall, and near Alston, Cumberland. A green variety occurs at Platten in Bohemia. The mineral is also found at Prince's mine, Lake Superior, in calcite. When abundant, it is used for the manufacture of smalt. (Dana, ii. 407.)

COBALT-BLUE. A pigment of a fine blue colour, like that of ultramarine, obtained by mixing the solution of a cobalt-salt, perfectly free from iron and nickel, with a solution of pure alum, precipitating with an alkaline carbonate, carefully washing the precipitate, then drying and igniting it strongly. It is a compound of protoxide of cobalt and alumina, and is used both as oil and water colour.

COBALT-GLANCE. See COBALTINE.

COBALT-GREEN. *Rinman's Green.* — A permanent green pigment prepared by precipitating a mixture of the sulphates of zinc and cobalt with carbonate of sodium, and igniting the precipitate after thorough washing; — or by mixing a solution of nitrate of cobalt with oxide or nitrate of zinc, then evaporating and igniting.

COBALTINE. *Cobalt-glance, Glance-cobalt, Silver-white cobalt, Cobalt gris.*— A native sulpharsenide of cobalt, Co^2AsS or $CoAs\,.\,CoS^2$, occurring in forms of the regular system, viz. the cube, octahedron, pentagonal dodecahedron, and several combinations of these forms. Cleavage parallel to the cubic faces. Also massive, granular or compact. Specific gravity = 6—6·3. Hardness = 5·5. Fracture imperfect, conchoïdal, uneven. Opaque, with metallic lustre. Colour silver-white, inclining to copper-red, occasionally tarnished. Streak, greyish-black. Brittle.

Before the blowpipe, it gives off fumes of arsenic, and yields, after roasting, a dull black feebly magnetic globule, which colours borax blue. It dissolves in warm nitric acid leaving a residue of arsenious acid.

Analyses.—*a*, from Skutterud by Stromeyer; *b*, from Siegen by Schnabel; *c*, from Orowitza in the Banat by Huberdt; *d*, from the same by Patera; *e*, from Skutterud by Ebbinghaus; *f*, from Siegen by Schnabel. (*Rammelsberg's Mineralchemie*, p. 60.)

	Co	Fe	As	Sb	S	
a . .	33·10	3·23	43·46	. .	20·08	= 99·88
b . .	29·77	6·38	44·75	. .	19·10	= 100·00
c . .	30·37	5·75	44·13	. .	19·75	= 100·00
d . .	32·03	4·56	43·63	. .	19·78	= 100·00
e . .	32·60	3·47	43·68	. .	20·58	= 100·34
f . .	8·67	25·98	42·53	2·84	19·98	= 100·00

The formula Co^2AsS requires 35·5 Co, 45·2 As, and 19·3 S. In analysis *f*, three-fourths of the cobalt is replaced by iron.

Cobaltine occurs in large splendid crystals at Tunaberg, Riddarhyttan, and Hokansbö in Sweden, and at Skutterud in Norway. It is also found at Querbach in Silesia, Siegen in Westphalia, and several localities in Cornwall. This species and smaltine afford the greatest part of the smalt of commerce. The most productive mines are those of Vena in Sweden. (Dana, ii. 58.)

COBALT-MICA. Syn. with COBALT-BLOOM.

COBALT-PYRITES. See COBALT, SULPHIDES OF (p. 1050).

COBALT-VITRIOL. *Bieberite, Red Cobalt, Rhodalose.*—Hydrated native sulphate of cobalt, of somewhat variable constitution, found in stalactites, and crusts investing other minerals, in the rubbish of old mines at Bieber near Hanau, and at Leogang in Salzburg. It is translucent, with flesh-red or rose-red colour and vitreous lustre. A specimen analysed by Winkelblech (Ann. Ch. Pharm. xiii. 265), after being freed by solution and filtration from admixed manganous arsenate, yielded 29·05 SO^3, 19·91 Co^2O, 3·87 Mg^2O and 46·83 water, agreeing nearly with the formula $(Co^6Mg^2).(SO^4)^4. + 28\,aq.$

COBALT-YELLOW. This compound, discovered by Saint-Èvre in 1852 (Ann. Ch. Phys. [3] xxxviii. 177), and further examined by A. Stromeyer (Ann. Ch. Pharm. xcvi, 218), is produced by the action of nitrite of potassium on cobaltous salts. Saint-Èvre regards it as a compound of peroxide of nitrogen with cobaltous oxide and potash, $CoO.KO.2NO^4$ or $CoKO.(NO^2)^2$:

$$\underset{\text{Nitrate of cobalt.}}{CoNO^3} + \underset{\text{Nitric acid.}}{2HNO^3} + \underset{\text{Nitrite of potassium.}}{4KNO^2} = \underset{\text{Cobalt-yellow.}}{CoKO.(NO^2)^2} + \underset{\text{Nitrate of potassium.}}{3KNO^3} + \underset{\text{Nitric oxide.}}{2NO} + H^2O$$

Stromeyer on the other hand regards it as a basic potassio-cobaltic nitrite, $Co^2O^3.3KO.5NO^3$, or $\left.\begin{matrix}(NO)^{10}\\(Cco''')^2.K^6\end{matrix}\right\}O^{11}$, on which supposition its formation may be represented by the equation:

$$4\underset{\text{Nitrate of cobalt.}}{\left(\left.\begin{matrix}NO^2\\Co\end{matrix}\right\}O\right)} + 10\underset{\text{Nitrite of potassium.}}{\left(\left.\begin{matrix}NO\\K\end{matrix}\right\}O\right)} + O = \underset{\text{Cobalt-yellow.}}{\left.\begin{matrix}(NO)^{10}\\(Cco''')^2.K^6\end{matrix}\right\}O^{11}} + 4\underset{\text{Nitrate of potassium.}}{\left(\left.\begin{matrix}NO^2\\K\end{matrix}\right\}O\right)}$$

The compound is prepared: 1. By adding an alkaline solution of nitrite of potassium (obtained by passing the nitrous vapours evolved from a mixture of nitrate of potassium and starch into caustic potash) to an acid solution of nitrate of cobalt.—2. By adding potash, not in excess, to a solution of nitrate of cobalt, so as to throw down a blue basic salt (p. 1043), treating this with a slight excess of nitrite of potassium, and adding nitric acid in a thin stream from a pipette.—3. By treating nitrate of cobalt with a slight excess of potash, so as to throw down the rose-coloured hydrate, and passing nitric oxide gas into the mixture.—It forms a bright yellow crystalline powder composed of microscopic four-sided needles with pyramidal summits. It is insoluble in cold water, also in alcohol and ether, but when boiled with water, it gradually dissolves, with evolution of acid vapours, and the solution, if subsequently evaporated, yields a lemon-yellow salt of different composition. Nitric acid and hydrochloric acid do not act upon it in the cold, but decompose it at the boiling heat, with evolution of nitrous vapours. Sulphydric acid decomposes it very slowly, sulphide of ammonium immediately forming black sulphide of cobalt; when heated, it assumes an orange-yellow colour, gives off water and afterwards nitrous fumes, and leaves sesquioxide of cobalt mixed with nitrate of potassium.

Cobalt-yellow forms an excellent pigment for artistic purposes, having a beautiful colour, like that of sulphide of cadmium, great permanence, and mixing easily with other colours. Its formation affords also an excellent method of separating cobalt from other metals, especially from nickel (p. 1046).

When a solution of lead is mixed with nitrite of potassium and acetic acid, the liquid assumes a yellow colour, but no precipitation takes place; but on adding a cobalt-salt, a yellowish-green precipitate (brownish-black and crystalline from dilute solutions) is formed, whose composition is that of the yellow cobalt-compound, having half the potassium replaced by lead. (Stromeyer.)

COCA. The leaves of *Erythroxylon Coca*, a plant cultivated in the mountainous districts of Peru and Bolivia, and in some parts of Brazil, are extensively used by the inhabitants of those countries, and of other parts of South America, for chewing like tobacco, for which purpose they are mixed with burnt lime, or the ash of a peculiar plant, the *Chenopodium Quinoa*, according to Niemann. They possess powerful tonic and sedative properties, and the practice of chewing them is said to give great power of enduring fatigue, even on a scanty supply of food; but like the use of opium, it is apt to become an indispensable necessity, and ultimately produces all the baneful effects of a narcotic poison, such as hallucinations and premature decay both of body and of mind. The use of coca is said to prevail among ten millions of people in South America, the annual consumption amounting to thirty million pounds of the dry leaves. Coca leaves do not long retain their activity; indeed they are said to become useless after a year's keeping.

Coca leaves contain, according to Niemann (Arch. Pharm. [2] ciii. 120 and 291), a crystallisable basic substance called cocaïne, a volatile odoriferous substance, a peculiar tannic acid, cocatannic acid, and a waxy body, coca-wax.

The volatile constituent of coca leaves has a strong tarry, almost intoxicating odour. On distilling the leaves with water a slightly turbid distillate is obtained, from which no oil separates; but on saturating it with common salt and redistilling, a very small quantity of a white non-crystalline substance is obtained, which is volatile, fusible, lighter than water, and possesses in a very high degree the odour of the leaves.

Cocatannic acid remains in the aqueous decoction of the leaves after the cocaïne has been precipitated by carbonate of sodium, and is left as a brown-red amorphous substance when the liquid is evaporated. Its solution is coloured deep brownish-green by ferric chloride, and is precipitated by tartar emetic, or solution of white of egg, but not by gelatin; it reduces chloride of gold even in the cold.

Coca-wax is contained in the precipitate formed by lime in extract of coca leaves prepared with alcoholic sulphuric acid. It contains 80·2 per cent. carbon and 13·4 hydrogen, agreeing with the formula $C^{50}H^{50}O^{3}$, and with the composition of the wax from grass, and of that from *Syringa*, as determined by Mulder. If the precipitate be exhausted with ether, the ether evaporated, and the residue repeatedly boiled with alcohol, the solution on cooling deposits a wax, which is white, amorphous, very friable, and becomes strongly electric by trituration. It is insoluble in water, dissolves slowly in boiling alcohol, easily in ether, sometimes, though rarely, remaining in a somewhat crystalline form when the ethereal solution is evaporated. It melts at 70° C., and decomposes when heated. Aqueous alkalis do not act upon it, but melting hydrate of potassium decomposes and dissolves it.

The substance mixed with coca leaves, to render them fit for chewing, is called *Llipta*. According to Niemann, it is the ash of *Chenopodium Quinoa*. Gädeke found it in 40·0 K^2O, 17·7 Na^2O, 5·6 Mg^2O, 0·2 Fe, 4·5 P^2O^5, 1·8 SO^3, 2·5 Cl, 6·7 SiO^2, 3·0 CO^2, 13·5 sand, 1·0 water, and a trace of organic matter. (Handw. d. Chem. ii. [2] 123.)

COCAÏNE. $C^{16}H^{19}NO^{4}$ or $C^{32}H^{19}NO^{8}$. (Niemann, Ann. Ch. Pharm. cxiv. 213.) —An alkaloïd obtained from coca leaves, resembling atropine in many of its properties. Niemann assigns to it the formula $C^{32}H^{20}NO^{8}$; but this is improbable, because the sum of the atoms of H and N is an odd number.

Cocaïne is prepared by digesting coca leaves with 85 per cent. alcohol containing a small quantity of sulphuric acid, mixing the expressed mass with milk of lime, neutralising the filtrate with sulphuric acid, evaporating off the alcohol, mixing the residue with water, precipitating the resulting yellow-brown solution with carbonate of sodium, treating the brown precipitate of impure cocaïne with ether, and evaporating. Cocaïne then remains, partly amorphous, partly crystalline, and may be purified by repeated treatment with alcohol.

Cocaïne crystallises in small, colourless, inodorous prisms; it has a slightly bitter taste, and produces temporary insensibility on the part of the tongue with which it comes in contact. It is soluble in 704 pts. of water at 12° C., more soluble in alcohol, and still more in ether. It melts at 98° C., and solidifies to a transparent mass, which gradually becomes white and crystalline. At a higher temperature, a very small portion appears to volatilise undecomposed, but the greater part is decomposed, yielding ammoniacal products. Cocaïne dissolves without colour in strong nitric, hydrochloric, and sulphuric acid, the last solution only becoming black when heated.

Cocaïne is strongly alkaline; it dissolves in dilute acids, and neutralises them completely. Its salts do not crystallise readily, the hydrochlorate, however, more easily than the others. Solutions of cocaïne-salts yield with *caustic alkalis*, a white precipitate soluble only in a large excess of fixed alkali, more soluble in ammonia. *Carbonate of sodium* forms a precipitate insoluble in excess. *Carbonate of ammonium* a precipitate easily soluble in excess. *Acid carbonate of potassium* and *phosphate of sodium* produce a red precipitate. *Sulphocyanide of potassium* produces but a slight turbidity; *picric acid* forms a sulphur-yellow precipitate, which gradually aggregates into resinous lumps; *tannic acid*, on addition of hydrochloric acid, forms a white precipitate, which aggregates in a similar manner; *mercuric chloride* and *potassio-mercuric iodide* produces white precipitates; *iodine-water* a kermes-brown; *iodide of potassium* containing iodine, a dark-brown precipitate; *trichloride of gold* and *dichloride of platinum* yield precipitates with the hydrochlorate; *protochloride of tin* produces a white precipitate, even in slightly acid and dilute solutions.

In most of these reactions, cocaïne closely resembles atropine (i. 474); the latter, however, is not precipitated by carbonate of ammonia, or in acid solutions by stannous chloride; the two bases differ also in their reactions with gold and platinum-salts, and in their melting points, that of cocaïne being 6° C. higher than that of atropine.

Hydrochlorate of Cocaïne crystallises in white slender needles, easily soluble in water; it has a bitter taste and produces on the tongue the peculiar action of the base itself, but in a higher degree. The solution, even when very dilute, is precipitated by *chloride of gold*, yielding the compound $C^{16}H^{19}NO^4.HCl.AuCl^3$, which crystallises from alcohol in gold-yellow scales or laminæ. This gold-salt melts when heated, and then yields a sublimate of benzoic acid, affording a very characteristic reaction. The *chloroplatinate* is a yellow-brown flocculent precipitate, which soon becomes crystalline, and is nearly insoluble in hydrochloric acid.

Acetate of Cocaïne crystallises readily; the *nitrate* with difficulty. The *sulphate* remains when its solution is evaporated, as a colourless varnish-like mass, which becomes crystalline after a while; it is permanent in the air.

COCATANNIC ACID.—COCA-WAX. See COCA (p. 1059).

COCCIN. A peculiar nitrogenous substance existing, according to Pelletier and Caventou, in cochineal, and forming, as it were, the flesh of the insect; it resembles gelatin in some of its characters, albumin and fibrin in others.

COCCINITE. Haidinger's name for the reddish-brown mineral, with adamantine lustre, from Casas Viejas in Mexico, which Del Rio regards as mercuric iodide. It melts and sublimes with facility.

COCCINNIC ACID. A volatile fatty acid existing, according to Pelletier and Caventou, in cochineal.

COCCINONIC ACID. A derivative of euxanthic acid (p. 712).

COCCODEA VIRIDIS. This plant contains a green colouring matter differing from chlorophyll. (Salm-Horstmar, Pogg. Ann. xciv. 466; cxv. 176.)

COCCOGNIC ACID. An acid contained, according to Göbel (Buchn. Repert. viii. 203), in the seeds of *Daphne Gnidium.* It is dissolved by water from the alcoholic extract; crystallises in colourless, slightly acid prisms; does not precipitate lime-water, or the solutions of chloride of barium, acetate of lead, or ferrous sulphate.

COCCOLITE. A name applied to certain granular varieties of augite.

COCCOLOBA UVIFERA. The plant which yields American kino.

COCCULIN. Syn. with PICROTOXIN.

COCCULUS INDICUS. *Graine of Paradise.*—The fruit of the *Cocculus suberosus* (Dec.), *Menispermum cocculus* (Linn.), *Anamirta cocculus* (Wight and Arnott). It possesses strong narcotic and poisonous properties, due to the presence of a bitter substance, picrotoxin ($C^5H^6O^2$), of which it contains about $\frac{1}{50}$ of its weight. It is used to adulterate beer, and is sometimes thrown into water to intoxicate or kill fish; it is occasionally employed in medicine. (See *Ure's Dictionary of Arts, Manufactures and Mines*, i. 786; also the article BEER in this Dictionary, i. 537.)

COCCUSIC ACID, $C^8H^8O^5$, is the acid corresponding to nitrococcusic acid, a product of the action of nitric acid on carmine (i. 804); it has not yet been obtained in the separate state.

COCHINEAL. *Cochenille, Coccionella.*—Several insects of the genus *Coccus*, especially the *Coccus cacti* or cochineal insect, yield a splendid colouring matter, extensively used for dyeing and the preparation of pigments. The cochineal insect lives on various plants of the genus *Opuntia*, especially on the nopal, *Opuntia decumana*, *O. cactus*, and *O. monacantha*. It is a native of Mexico, but its cultivation has been introduced into many other hot countries, namely, the West Indies, Teneriffe, Madeira, Algeria, Java: in colder climates it does not thrive. The female insects only are collected; they are killed either by drying in the sun, on hot plates, or in stoves, or by immersing them for a short time in hot water. The last method yields a cochineal of somewhat red-brown aspect, whereas if the insects have been killed by drying, it has more of a blackish or ash-grey colour, with a silvery surface; the latter is preferred. The dry cochineal is freed from dust and adhering impurity by shaking it in sacks; the fine dust is then removed by sifting, and the larger and smaller lumps in the remaining mass are separately sorted.

Other species of coccus probably contain the same colouring matter, but in smaller quantity and more contaminated with foreign substances.

Cochineal occurs in commerce in nearly egg-shaped grains 1 or 2 lines long, somewhat hollowed below and arched above, about 70,000 going to the pound. It is inodorous, very friable, and contains within it a dark red granular mass, which yields a powder of a fine deep red colour; it has a bitter, slightly astringent taste, and leaves but a small quantity of ash when burnt. In water, it swells up considerably, the shape of the insect and its three pairs of legs then becoming distinctly visible.

The first investigation of cochineal was made by John (*Chemical Tables*, p. 127), who found in it 50 per cent. coccus-red (carmine), 10 waxy fat, 1·5 inorganic salts (chlorides of potassium and ammonium, and phosphates of calcium, iron, and magnesium), 28·0 animal matter, and 10·5 water. According to Pelletier and Caventou (Ann. Ch. Phys. vii. 90; viii. 255), it contains a peculiar nitrogenous matter, coccin (p. 54), which forms, as it were, the flesh of the insect, and an acid, not examined, to which they give the name of coccinic acid.

The colouring matter of cochineal is carminic acid (i. 804).

The watery extract likewise contains a crystallisable nitrogenous substance, $C^9H^{11}NO^3$, homologous with tyrosine, ($C^8H^9NO^3$), and very similar to it in appearance and reactions. It remains in the aqueous decoction of cochineal after the carminic acid has been precipitated by acidulated acetate of lead, and may be separated by removing the excess of lead from the filtrate with sulphuretted hydrogen, and evaporating to a syrup; it then separates in a crystalline mass, and an additional quantity may be obtained by further concentration. It is insoluble in alcohol and ether, soluble without decomposition in hydrochloric acid, decomposed by strong nitric acid, the liquid yielding crystals of a new acid on evaporation; hot nitric acid produces a more thorough decomposition, with separation of charcoal. The chalky substance dissolves in alkalis, and is separated therefrom by acids. It does not appear to form definite compounds either with acids or with bases.

The mother-liquor from which the whole of the chalky substance has been removed, dries up to a soft mass amounting to 10 or 12 per cent. of the cochineal; part of this mass is soluble in alcohol, the remainder in water.

Cochineal boiled with water yields a deep red liquid, which assumes a reddish-yellow colour when mixed with *tincture of galls* or with strong *acids*, and a beautiful violet with *lime-water;* it is precipitated violet-blue by *neutral acetate of lead*, bright red by *ammonia*, dark black-brown by *ferric chloride;* olive-green by a larger quantity, deep red by *alum*. After the cochineal has been thoroughly boiled with water, a brownish animal substance remains.

The red colour of cochineal is likewise extracted by alcohol.

The chief use of cochineal is for the preparation of carmine and carmine-lakes (i. 804). It is likewise employed for dyeing wool and silk scarlet (the fabric being steeped first in annotto, then in a decoction of cochineal containing cream of tartar and stannoso-stannic chloride), or crimson (cochineal with tartar and tin-salt). Cochineal is likewise used for the preparation of rouge, of painters' colours, and of red ink, and for colouring tooth-powder, confectionery, liqueurs, &c.

Cochineal varies much in colouring power, according to its source and mode of preparation. The relative quantities of colouring matter in different samples may be estimated approximately by the depth of colour of a solution obtained by heating 1 gramme of cochineal in the water-bath for an hour, with 1000 grammes of water and 20 drops of a saturated solution of alum; also by the depth of colour which the same extract will impart to wool. Robiquet estimated the amount of colouring matter by means of a graduated solution of chlorine; Anthon by a graduated solution of an alumina-salt.

A better method is that of Penny, depending on the action of ferricyanide of potassium. 1 gramme of cochineal is extracted with 50 cub. cent. of dilute potash-solution: the extract is further diluted with 100 cc. of cold water; and the purple solution thereby obtained is mixed, when cold, with a graduated solution of ferricyanide of potassium (1 grm. of the salt to 200 cc. of solution), till its colour changes to dark brown. All these methods yield only relative results for comparing different sorts of cochineal one with the other. (See *Ure's Dictionary of Arts, Manufactures and Mines*, i. 786; Handw. d. Chem. 2te Aufl. ii. [2] 127.)

COCHINEAL-RED is properly carmine; the same term is, however, applied to a splendid red artificial colour, which contains a considerable quantity of arsenate of aluminium, and is therefore highly poisonous.

COCHLEARIA. A genus of cruciferous plants, including horse-radish and scurvy-grass, distinguished by their acridity, arising from the presence of volatile oils, similar to, or identical with, volatile oil of mustard (sulphocyanate of allyl).

Cochlearia Armoracia. Horse-radish.—The volatile oil of this plant, when purified, is identical with oil of mustard. It appears to exist in the root ready formed, and may be obtained by bruising the root to a pulp, and distilling it *per se.* The best mode of preparation, however, is to distil 3 pts. of the finely chopped root with 2 pts. water, in a glass vessel (if a copper still be used, only a small quantity of oil is obtained, in consequence of the formation of metallic sulphide). 100 pts. of the root thus treated yield about 0·05 pt. of crude oil, which may be purified by rectification with water and drying over chloride of calcium. The purified oil is colourless or pale yellow; has a density of 1·01; smells like oil of mustard, and contains 48·41 per. cent. C, and 5·26 H (sulphocyanate of allyl, $C^3H^5.CNS$, requires 48·49 C and 5·05 H). The crude oil is light yellow, of the consistence of cinnamon-oil, heavier than water, evaporates quickly, has an intolerable odour of horse-radish, tastes sweet at first, afterwards sharp and burning, and inflames the lips and tongue. When kept under water for a year, it disappears, and silvery needles are formed, which smell like horse-radish, excite irritation in the throat, melt and volatilise when heated, and dissolve but slowly in alcohol. Oil of horse-radish is decomposed by nitric acid, sulphuric acid, and chlorine. It yields sinapoline with oxide of lead, and thiosinnamine with ammonia. It dissolves slightly in water, the solution forming a brown precipitate with acetate of lead, black with nitrate of silver. It dissolves readily in alcohol. (Gm. x. 55).

Cochlearia officinalis. Common scurvy grass.—The herb of this plant contains 92·2 per cent. water, and yields 1·6 per cent. ash, which, according to Geiseler, is very rich in potash, but, according to Braconnot, contains soda. The base is partly combined with nitric acid and, according to Braconnot, with an organic acid resembling malic acid.

Oil of scurvy-grass, *Oleum cochleariæ*, obtained by distilling the herb with water, is yellow, pungent, of specific gravity 0·942 (Geiseler), boils between 156° and 159° C. (Simon). It dissolves easily in alcohol, and the alcoholic solution, *Spiritus cochleariæ*, may be obtained by distilling the bruised herb with alcohol. According to Geiseler (Arch. Pharm. cxlvii. 136, 257), the oil is an oxysulphide of allyl, C^6H^5SO, and yields with ammonia a crystalline compound, $C^6H^5SO.NH^3$. [These formulæ are doubtful.] The oil does not exist ready formed in the plant, but is produced by the action of myrosin in presence of water, on a peculiar substance existing therein. According to Winckler (Jahrb. pr. Pharm. xviii. 319), this substance is neutral, and is converted into the volatile oil by the joint action of myrosin and lime.

Scurvy-grass camphor, or Cochlearin, $C^6H^7O^2$(?), is a crystalline substance sometimes deposited from *Spiritus cochleariæ*, and from the water which has been distilled off the plant. It forms small, nacreous, shining laminæ or needles, having a faint odour, and sharp aromatic taste. Specific gravity = 1·248. It melts at 45° C., sublimes without alteration, dissolves lightly in pure water, easily in water containing carbonate of potassium, also in alcohol and ether. (Maurach, Repert. Pharm. xcix. 128.)

Cochlearia Draba, Whitlow Pepperwort, yields, by distillation with water, a volatile oil, similar to that obtained from radish-seeds. (Ploss, Ann. Ch. Pharm. lviii. 40.)

Cochlearia anglica. English scurvy-grass.—The fresh herb of this plant contains, according to T. J. Herapath (Chem. Soc. Qu. J. ii. 4), 2·42 per cent. ash; the dry herb 21·1 per cent. ash; of which 78·1 per cent. are soluble, and 21·9 per cent. insoluble in water. 100 parts of the ash contain:

Soluble in Water.		*Insoluble in Water.*	
Potash	0·1	Carbonate of calcium	7·2
Soda	7·7	Carbonate of magnesium	1·3
Carbonic acid (CO^2)	3·6	Phosphate of calcium	10·3
Sulphuric acid (SO^3)	3·1	Ferric phosphate	0·6
Chloride of sodium	63·6	Silica	2·5

COCHLEARIN. See COCHLEARIA OFFICINALIS.

COCINIC ACID. *Cocostearic acid. Cocylic acid. Coconustalgsäure.*—A fatty acid, or probably a mixture of acids, obtained from cocoa-nut oil.

Bromeis (Ann. Ch. Pharm. xxxv. 277), by saponifying cocoa-nut fat, decomposing the soap with an acid in the usual way, pressing the resulting fatty acid between paper, and recrystallising from alcohol, obtained a nearly inodorous fatty acid, which melted at 35° C., solidified to a porcelain-like mass translucent at the edges, and distilled without decomposition. Saint-Èvre (Ann. Ch. Phys. [3] xx. 95) decomposes the soda-soap of cocoa-nut oil with acetate of lead; exhausts the lead-soap with ether; decomposes the undissolved soap with an acid; and crystallises the fatty acid from alcohol. From a saturated solution in aqueous alcohol, it crystallises, on cooling, in needles; but from a solution in strong alcohol, by evaporation, in amorphous masses. It melts at 34·5° C., and volatilises without decomposition only in a stream of gas.

Bromeis assigned to his cocinic acid the formula $C^{27}H^{27}O^4$, but his analysis, calculated according to the more recently determined atomic weight of carbon ($C = 6$), gives rather $C^{26}H^{26}O^4$, or $C^{13}H^{26}O^2$. Heintz has since announced the separation of an acid of the same composition from spermaceti. Fehling obtained from cocoa-nut oil an acid resembling the acid prepared by Bromeis in appearance and melting point, and corresponding exactly to the formula $C^{13}H^{26}O^2$.

Saint-Èvre, on the other hand, assigned to the cocinic acid which he obtained, the formula $C^{11}H^{22}O^2$, though it agrees very closely with that of Bromeis in the melting point.

Heintz regards the acid $C^{13}H^{26}O^2$ from cocoa-nut oil, and likewise that obtained by himself from spermaceti, as a mixture, especially on account of its melting point, which is lower than that of lauric acid ($C^{12}H^{24}O^2$); whereas if it were really a definite acid, its melting point would be intermediate between those of lauric acid (44° C.) and myristic acid, $C^{14}H^{28}O^2$ (54° C.). He finds, indeed, that a mixture of 14 pts. lauric and 2 pts. myristic acid melts at about 35° C. Saint-Èvre's formula, $C^{11}H^{22}O^2$, is on this account more probable.

Cocinate of barium, crystallised from boiling alcohol, is, according to Bromeis, $C^{13}H^{25}BaO^2$. *Cocinate of silver*, $C^{13}H^{25}AgO^2$ (Bromeis), $C^{11}H^{21}AgO^2$ (Saint-Èvre), is obtained by precipitation from alcoholic solutions, in white flocks melting at 55° C., soluble in ether, sparingly soluble in alcohol.

Cocinate of ethyl, $C^{13}H^{25}(C^2H^5)O^2$ or $C^{11}H^{21}(C^2H^5)O^2$, obtained by passing hydrochloric acid gas into a hot alcoholic solution of cocinic acid, washing the product with weak alkali, and drying over chloride of calcium, is a liquid having a faint-yellow colour, a very pungent odour of apples, and a sweet mawkish taste.

COCININ. *Cocinate of glyceryl.*—The name of the neutral fat corresponding to cocinic acid. The separate identity of such a fat, like that of the acid itself, must, for the present be considered doubtful. Brandes (Ann. Ch. Pharm. xv. 115), by expressing the fat from cocoa-nuts, and crystallising it repeatedly from boiling alcohol, obtained a snow-white laminar crystalline fat, of specific gravity 0·92 at 8° C., less soluble in pure than in common ether, soluble in 40 pts. absolute alcohol at 20° C., about 12 pts. at 44° C., sparingly soluble in aqueous alcohol of 0·75 in the cold, more soluble in the same when warm; crystallising on cooling; decomposed by dry distillation.

COCINONE. A product of the decomposition of neutral cocinate of calcium, consisting, according to Delffs (Pogg. Ann. lxxxvi. 587), of $C^{21}H^{42}O$, and therefore the acetone of Saint-Èvre's cocinic acid $C^{11}H^{22}O^2$. When purified by recrystallisation from boiling alcohol, it forms colourless, inodorous, tasteless laminæ, melting at 38° C., and boiling at a temperature beyond the range of the mercurial thermometer.

COCOA-NUT OIL. This oil or fat is obtained by pressure from the fruit of certain cocoa-palms, *Cocos nucifera*, *C. butyracea*, &c., and is imported in large quantities into Europe for the manufacture of soap. It is whitish, of unctuous consistence, with a peculiar disagreeable odour of volatile fatty acids, and a mild taste; it melts at 20° C., dissolves with aid of heat in alcohol and ether, readily in oils, both fixed and volatile, benzene, &c.

Cocoa-nut oil quickly becomes rancid, and is easily saponified. It is a mixture of several glycerides, containing also free fatty acids. By saponification it yields both fixed and volatile fatty acids. The volatile acids, which may be separated by distilling the mixture of free fatty acids with water, consist chiefly of caprylic acid mixed with small quantities of caproic and capric acids. The fixed fatty acids of cocoa-nut oil are partly liquid at ordinary temperatures, partly solid. The former have not been particularly examined; of the latter, several may be isolated by crystallisation from alcohol, viz. lauric acid, $C^{12}H^{24}O^2$, which may be obtained pure, with the melting point 43° C., by fractional precipitation of the soda soap (Oudemans, J. pr. Chem.

lxxxi. 367); the acid, $C^{11}H^{22}O^2$, which was obtained from the oil by Saint-Évre, and $C^{13}H^{26}O^2$ by **Bromeis**, (see COCINIC ACID, p. 57); **myristic acid**, $C^{14}H^{28}O^2$, likewise exists in considerable quantity in cocoa-nut oil. The acid actually obtained had very nearly the composition of myristic acid, and melted at 49° C., the melting point of the pure acid being 53·8° (**Fehling**, Ann. Ch. Pharm. liii. 399). **Görgey** (*ibid.* civ. 25) likewise found a fatty acid, $C^{15}H^{30}O^2$, melting at 56° C., which, from the examination of the silver-salt, he regarded as a mixture of myristic and palmitic acids. Fehling also found pure **palmitic acid**. **Stearic acid** is probably present in small quantity.

The solid fats of cocoa-nut oil are separated from the more liquid fats by pressure, and used for the manufacture of candles.

The solid fatty acids of cocoa-nut oil are converted, by prolonged treatment with nitric acid, into a mixture of acids of the series $C^nH^{2n-4}O^4$, viz. anchoic, suberic, pimelic, adipic, succinic acid, and an oily mass containing nitrocapric and nitrocaprylic acids.

CODEINE. $C^{18}H^{21}NO^3 + H^2O$ or $C^{36}H^{21}NO^6 + 2HO$.—A non-volatile organic base contained in opium. It was discovered by **Robiquet** in 1832 (Ann. Ch. Phys. [2] li. 259), and has been further examined by **Couerbe** (*ibid.* lix. 158), **Regnault** (*ibid.* lxviii. 136), **Gregory** (Ann. Ch. Pharm. xxvi. 44), **Will** (*ibid.* 44), **Gerhardt** (Rev. Scient. x. 203; *Traité*, iv. 40), and especially by **Anderson** (Ed. Phil. Trans. xx. [1] 57).

Preparation.—1. The aqueous infusion of opium, evaporated to a syrup, is mixed with solution of chloride of calcium; the mass is diluted with water; the resulting meconate of calcium is separated, washed several times with small quantities of water and pressed; and the liquid thus obtained is evaporated, lumps of marble being thrown into it to neutralise the free acid. Fresh quantities of meconate of calcium then separate, and the decanted liquid, if left at rest, deposits crystals of hydrochlorate of morphine and hydrochlorate of codeine. These crystals are dissolved in water, and the solution, after purification with animal charcoal, is precipitated by ammonia, which separates the greater part of the morphine, leaving the codeine in solution. The filtered liquid is evaporated over the water-bath to expel the excess of ammonia, the morphine salt remaining in solution being at the same time precipitated; the saline solution is concentrated and precipitated by caustic potash; and the precipitate of codeine is washed, dried, and dissolved in ether, whence it is deposited in crystals. (**Robiquet.**)

2. To obtain the whole of the codeine from the mother-liquor which remains after the morphine has been removed by precipitation with ammonia, as just described, it is necessary to get rid of the sal-ammoniac with which it is mixed. This may be effected by repeatedly concentrating the liquid—the greater part of the hydrochlorate of codeine then separating out, while the sal-ammoniac remains dissolved—and decomposing the remaining sal-ammoniac with caustic potash. By repeating the crystallisation a certain number of times, the hydrochlorate of codeine might be obtained quite free from sal-ammoniac; this, however, would occasion the loss of a considerable quantity of codeine, inasmuch as the two hydrochlorates do not differ greatly in solubility; but if the crystallisation be discontinued at an earlier stage, the greater part of the sal-ammoniac may be removed without loss of codeine. The crystals of hydrochlorate of codeine are then to be dissolved in boiling water, and a strong solution of caustic potash added in excess, which will precipitate the codeine, partly as an oil which gradually solidifies, partly in the crystalline state as the liquid cools. The mother-liquor yields by evaporation a fresh crop of crystals of codeine, and lastly, after reduction to a very small bulk, it becomes filled, on cooling, with long silky needles of morphine, which had been retained in solution by the excess of potash. (**Anderson.**)

3. Opium is exhausted with cold water, the morphine precipitated by ammonia, the meconic acid by chloride of calcium, and the colouring matter by subacetate of lead. The liquid filtered from the lead-precipitate is freed from lead by sulphuric acid and filtered again; the filtrate is mixed with excess of potash; the mixture left to stand in the air till carbonate of potassium has formed; and the whole agitated with ether, which extracts the codeine. (**Winckler**, Répert. Pharm. xliv. 459.)

4. **Merck** (Ann. Ch. Pharm. xi. 279) precipitates the mixture of the hydrochlorates of codeine and morphine with pure soda; treats the precipitate with cold alcohol; saturates the alcoholic solution with sulphuric acid; removes the alcohol by distillation, and adds cold water to the remaining liquid as long as it produces turbidity; then filters, evaporates to a syrup, and agitates the residue with excess of potash and with ether. The codeine dissolves in the ether and is deposited by spontaneous evaporation; it is finally treated with alcohol, to free it from an oily substance which prevents crystallisation.

Purification.—Impure crystals of codeine are purified by dissolving them in hydrochloric acid, boiling with animal charcoal, reprecipitating with caustic potash and finally dissolving the precipitate in ether containing water, in order to free the codeine from the last trace of morphine; the ether used must, however, be free from alcohol, otherwise a syrupy liquid remains, on evaporation, which cannot be made to crystallise. If anhydrous ether be used, the codeine dissolves much more slowly (Handw. d. Chem. ii. [3] 136). 100 pounds of opium yield from 6 to 8 oz. of codeine (Robiquet). The proportion of codeine in opium is from $\frac{1}{30}$ to $\frac{1}{18}$ of that of the morphine. (Anderson.)

Properties.—Codeine crystallises from anhydrous ether in small anhydrous rectangular octahedrons, truncated and modified in various ways. From hydrated ether or alcohol, and from water, it separates in hydrated crystals of the trimetric system. Those deposited from alcohol exhibit the combination $\infty P \,.\, 0P \,.\, \bar{P}\infty \,.\, \breve{P}\infty$; those from water, the combination $\infty P \,.\, \breve{P}\infty \,.\, \frac{1}{2}\breve{P}\infty$. Inclination of $\infty P : \infty P = 87° 40'$; $\bar{P}\infty : 0P = 141° 37'$; $\breve{P}\infty : 0P = 140° 23'$; $\frac{1}{2}\breve{P}\infty : 0P = 157° 25'$. Cleavage parallel to 0P. (Kopp, *Krystallographie*, 266.)

Codeine dissolves in water much more readily than morphine, especially in boiling water. 100 pts. of water at 15° C. dissolve 1·26 pts. codeine. When heated with a quantity of water less than sufficient to dissolve it, it melts to an oily mass, which remains at the bottom of the liquid. It dissolves easily in alcohol and hydrated ether, less easily in anhydrous ether. The alcoholic solution deflects the plane of polarisation of a luminous ray strongly to the left; $[\alpha] = -118·2°$; acids have scarcely any effect on the rotatory power.

Codeine is quite insoluble in potash; it dissolves in ammonia, but not to a greater extent than in pure water.

Anhydrous codeine contains:

	Calculated.		Robiquet.	Couerbe. (*mean.*)	Regnault.	Gregory. (*mean.*)	Will.	Anderson. (*mean.*)
C^{18}	216	72·24	70·36	71·84	73·31	73·05	73·27	72·01
H^{21}	21	7·02	7·58	7·37	7·19	7·21	7·25	7·09
N	14	4·68	5·35	—	4·89	4·89	—	4·50
O^3	48	16·06	—	—	—	—	—	—
	299	100·00						

The hydrated crystals contain, according to Gerhardt's analysis, 67·82 per cent. C, and 7·46 H, agreeing nearly with the formula $C^{18}H^{21}NO^3 + H^2O$, which requires 68·13 C, 7·25 H, 4·41 N, and 20·21 O.

Codeine is a strong base, quickly restoring the blue colour of reddened litmus, and precipitating the salts of lead, iron, copper, cobalt, nickel, &c.

In its action on the animal economy, codeine resembles morphine in many respects. According to Robiquet, doses of 0·02 to 0·03 grm. produce in 24 hours, especially in excitable persons, a sensation of comfort and repose, and a refreshing sleep, whereas doses of 0·15 to 0·12 grm. produce heavy sleep, with a feeling of intoxication after waking—sometimes also nausea and vomiting; more than 0·2 grm. cannot be taken in 24 hours without danger of serious consequences.

Codeine is said to be sometimes adulterated with sugar-candy; this impurity may be detected by its greater solubility in water, its smaller solubility in alcohol, and its very different action on polarised light. According to Robiquet, a solution of 0·500 grm. pure codeine in 100 cub. cent. alcohol of at least 56 per cent. gives, for the transition tint, a deflection of 11° to the left.

Decompositions.—1. When codeine is dissolved in excess of *sulphuric acid* of medium strength, and the solution is digested in a sand-bath, it acquires a dark colour, and after a while yields a precipitate with carbonate of sodium, which is not the case with codeine-salts in their ordinary state. The precipitate thus formed consists of amorphous codeine, which, after washing with water, solution in alcohol, and precipitation by water, forms a grey powder with more or less green reflection, insoluble in water, easily soluble in alcohol, and precipitated therefrom by ether. It melts at 100° C. to a black resinous mass. It dissolves easily in acids, forming amorphous salts, which dry up by evaporation to brown resins. If the action of the sulphuric acid on the codeine be prolonged, a dark green substance is obtained.

2. *Nitric acid*, according to its degree of concentration, forms with codeine either a basylous nitro-compound (p. 1067), or a yellow resin soluble in alkalis.

3. *Chlorine* and *bromine* form substitution-products (p. 1065).

4. *Iodide of ethyl* heated with codeine forms hydriodate of ethyl-codeine.

5. Codeine gently heated with *hydrate of potassium*, yields several volatile alkalis, viz. ammonia, methylamine and tritylamine, in variable proportion, according to the manner in which the process is conducted. A volatile crystalline base is likewise produced in small quantity, and a brown or black substance remains.

Salts of Codeine.—Codeine is a mono-acid base, dissolving readily in acids, and yielding for the most part crystallisable salts. They are very bitter, are not reddened by nitric acid, and do not impart a blue colour to ferric salts. *Potash* precipitates codeine from their solutions; *ammonia* does not precipitate them immediately, but gives rise, after some time, to the separation of small transparent crystals of codeine. *Infusion of gall-nuts* precipitates codeine-salts immediately.

Chromate of Codeine is easily obtained in beautiful yellow needles.

Hydrochlorate of Codeine, $C^{18}H^{21}NO^3.HCl + 2H^2O$.—A somewhat concentrated solution of codeine in hydrochloric acid, solidifies completely on cooling; a more dilute solution deposits radiate groups of short needles, exhibiting under the microscope the form of prisms with four faces, terminated by dihedral summits. The crystals dissolve in 20 pts. of water at 15·5°C., and in less than their weight of boiling water. They give off $\frac{1}{2}$ of their water at 100° C., the remainder at 121°, part of the acid, however, going off at the same time.

Chloro-aurate of Codeine, obtained by mixing the solutions of the component salts, is a reddish or light-brown precipitate, moderately soluble in hydrochloric acid.

The *Chloromercurate* is obtained in like manner, as a precipitate, soluble in boiling water and in alcohol, and deposited in stellate groups on cooling.

The *Chloroplatinate*, $C^{18}H^{21}NO^3.HCl.PtCl^2 + 2H^2O$ separates on adding dichloride of platinum to a moderately concentrated solution of hydrochlorate of codeine, as a light-yellow powder, which, if left in the liquid or kept moist on the filter, gradually becomes crystalline, and of an orange-red colour. From very dilute solutions, the double salt separates after some time in silky needles. It dissolves sparingly in cold water, and is decomposed by boiling water. It gives off $\frac{3}{4}$ of its water at 100° C., the rest at 120°, with incipient decomposition.

Hydriodate of Codeine. $C^{18}H^{21}NO^3.HI + H^2O$.—Long thin needles, soluble in about 60 pts. of cold water, much more soluble in boiling water. They do not give off any water at 100° C.

Hydrocyanate of Codeine is uncrystallisable.—The *hydroferrocyanate*, produced by mixing the alcoholic solutions of codeine and hydroferrocyanic acid, is a white precipitate which crystallises after a while in needles, and dissolves in excess of hydroferrocyanic acid. The *hydroferricyanate* produced by adding aqueous ferricyanide of potassium to hydrochlorate of codeine, is a very unstable crystalline compound.

Nitrate of Codeine, $C^{18}H^{21}NO^3.HNO^3$, is produced by slowly adding nitric acid of specific gravity 1·06 to pulverised codeine, carefully avoiding an excess of the acid, which would produce decomposition. It dissolves easily in boiling water, and separates on cooling in small prismatic crystals. It melts at a moderate heat, and decomposes at a higher temperature, leaving a difficultly combustible charcoal.

Oxalate of Codeine, $2C^{18}H^{21}NO^3.H^2C^2O^4 + 3H^2O$, is deposited on cooling, from a hot saturated solution in short prisms and sometimes in scales. It dissolves in 30 pts. water at 15·5° C., and in about half its weight of boiling water. It gives off its water at 100°, turns brown at about 121°, and decomposes completely at higher temperatures.

Phosphate of Codeine. $C^{18}H^{21}NO^3.H^3PO^4 + \frac{3}{2}H^2O$—A solution of ordinary phosphoric acid saturated with pulverised codeine does not crystallise by concentration, but on addition of strong alcohol immediately deposits scales or short prisms. It is very soluble in water.

Other phosphates of codeine appear also to exist.

Sulphate of Codeine, $2C^{18}H^{21}NO^3.H^2SO^4 + 5H^2O$ (or $C^{36}H^{21}NO^6.HSO^4 + 5HO$) crystallises in radiate groups of long needles, or by spontaneous evaporation, in flattened prisms. It dissolves in 30 pts. of cold water, and is very soluble in hot water. When pure, it is neutral to test-paper; but it is apt to retain a small quantity of acid, which may be separated by repeated crystallisation. The crystals belong to the trimetric system, $\infty P . \breve{P}\infty . \infty\bar{P}\infty$. Inclination of $\infty P : \infty P = 151° 12'$; $\infty\bar{P}\infty : \breve{P}\infty = 113° 45'$; $\breve{P}\infty : \breve{P}\infty = 133° 3'$; $\infty\bar{P}\infty : \infty P = 104° 24$. Cleavage parallel to $\infty\bar{P}\infty$.

Sulphocyanate of Codeine. $C^{18}H^{21}NO^3.HCyS + \frac{1}{2}H^2O$.—Radiate needles melting at 100° C., giving off 2·45 per cent. water (= $\frac{1}{2}$ at.) at 100° C.

Tartrate of Codeine is uncrystallisable.

Substitution-products of Codeine.

Bromocodeine. $2C^{18}H^{20}BrNO^3 + 3H^2O$ (Anderson *loc. cit.*)—Prepared by adding bromine-water in small successive portions to pulverised codeine. The codeine dissolves, and the solution loses the colour of bromine but acquires a characteristic reddish tint. On adding ammonia, the whole of the bromocodeine is precipitated as a silver-white powder, containing a small quantity of unaltered codeine. It may be obtained pure by repeated washing with cold water, solution in hydrochloric acid, precipitation with ammonia and crystallisation from alcohol.

Bromocodeine is nearly insoluble in cold water, rather more soluble in hot water, whence it separates on cooling in small prisms with dihedral summits. It is nearly insoluble also in ether, but dissolves easily in alcohol, especially at the boiling heat. Better crystals are obtained from alcohol diluted with an equal volume of water. The crystals are always very small, but of dazzling whiteness. They give off their water (6·66 per cent.) at 100° C. The anhydrous base gives by analysis 57·44 per cent. C, 5·44 H, and 21·5 Br, the formula $C^{18}H^{21}BrNO^3$, requiring 57·14 C, 5·29 H, 21·16 Br, 3·70 N, and 12·71 O.

Bromocodeine melts when heated, forming a colourless liquid, which decomposes at a somewhat higher temperature. It dissolves in cold sulphuric acid, the solution becoming dark coloured when heated. It is attacked by nitric acid, but much less quickly than codeine.

Hydrobromate of Bromocodeine, $C^{18}H^{20}BrNO^3.HBr + H^2O$, forms small prisms, sparingly soluble in cold water, very soluble in boiling water. It gives off its water at 100° C. The *hydrochlorate* forms radiate needles, resembling hydrochlorate of codeine. The *chloroplatinate*, $C^{18}H^{20}BrNO^3.HCl.PtCl^2$ (at 100° C.), is precipitated as a pale-yellow powder, insoluble in water and in alcohol (platinum, by analysis, 16·98 per cent.; by calculation 16·89).

Tribromocodeine, $C^{18}H^{18}Br^3NO^3$ (Anderson, *loc. cit.*)—When bromocodeine is subjected to the continued action of bromine-water in excess, a light-yellow precipitate of hydrobromate of tribromocodeine is formed, which redissolves at first, but becomes permanent on further addition of bromine. On leaving the liquid to itself for 24 hours and then adding more bromine, a fresh precipitate is formed, and this treatment must be repeated day after day as long as any further precipitate is thrown down by adding bromine. The yellow precipitate is then to be washed with cold water, and dissolved in hydrochloric acid; and the base precipitated by ammonia, purified by solution in alcohol, and precipitated by water.

Tribromocodeine thus prepared is an amorphous bulky powder, grey when dry, insoluble in water and ether, easily soluble in alcohol. It dissolves somewhat sparingly in cold, more easily in hot hydrochloric acid, a small portion however remaining undissolved, apparently from partial decomposition. It turns brown when heated on platinum-foil, and decomposes completely at its melting point, leaving a very slowly combustible charcoal.

Tribromocodeine is but a weak base; its salts are all soluble in water and amorphous. The *hydrobromate*, $2C^{18}H^{18}Br^3NO^3.3HBr$, obtained as above, is a light-yellow perfectly amorphous powder, sparingly soluble in cold, more soluble in hot water. The *chloroplatinate*, $C^{18}H^{18}Br^3NO^3.HCl.PtCl^2$, is obtained by precipitation, as a brown-yellow powder, insoluble in water and in alcohol (platinum, by analysis, 13·07 per cent.; by calculation, 13·29).

CHLOROCODEINE, $2C^{18}H^{20}ClNO^3 + 3H^2O$. (Anderson, *loc. cit.*)—Dry codeine treated with chlorine gas, yields a number of complex products, which have not been examined. By passing chlorine into the aqueous solution of codeine, a nearly black liquid is produced, from which ammonia throws down an amorphous resinous base. A more definite reaction is obtained by treating codeine with chlorate of potassium and hydrochloric acid. Finely pulverised chlorate of potassium is gradually added to a solution of codeine in hydrochloric acid at 65°—70° C. till the liquid yields a precipitate on addition of ammonia. Excess of ammonia is then added, which throws down chlorocodeine as a silver-white or generally somewhat yellowish crystalline powder, while a reddish liquid remains, containing products of a further decomposition. In this process, the same precautions must be observed as in the preparation of nitrocodeine (p. 1068). The chlorocodeine is freed from a small quantity of undecomposed codeine by solution in hydrochloric acid, boiling with animal charcoal, precipitation with ammonia, and crystallisation from a hot alcoholic solution.

Chlorocodeine resembles bromocodeine in most of its properties. It dissolves sparingly in boiling water, and crystallises on cooling in small prisms, which appear to be isomorphous with the crystals of bromocodeine. It is very soluble in strong alcohol, especially if hot; sparingly soluble in ether. The crystals give off their water (7·48 per cent.) at 100° C. The dried base gives by analysis 65·31 per cent. C, 6·11 H, and 10·32 Cl, the formula $C^{18}H^{20}ClNO^3$ requiring 64·76 C, 5·99 H, 10·64 Cl, 4·19 N, and 14·42 O.

Chlorocodeine dissolves without alteration in strong sulphuric acid; but the solution is carbonised by heat. Nitric acid also dissolves it, and the solution decomposes on boiling, though, much less easily than that of codeine, giving off nitrous gases and a very pungent vapour.

The *salts of chlorocodeine* resemble those of bromocodeine. The *chloroplatinate* is a pale yellow precipitate, which after drying at 200° C. yields 18·29 per cent

Pt.; agreeing with the formula $C^{18}H^{20}ClNO^3.HCl.PtCl^2$. The *sulphate*, $2C^{18}H^{20}ClNO^3, H^2SO^4 + 8H^2O$ is deposited from a hot solution in radiate groups of short prisms, very soluble in boiling water and in alcohol.

Cyanocodeine, $C^{18}H^{21}NO^3.Cy^2$ (Anderson, *loc. cit.*)—This compound, which is not a substitution-product like the preceding, but rather a cyanide of codeine, is produced when cyanogen gas is slowly passed into a concentrated alcoholic solution. The gas is abundantly absorbed, the liquid first turning yellow, then brown; the odour of cyanogen gradually disappears, and is replaced by that of hydrocyanic acid; and crystals are deposited, continually increasing in quantity, as the passage of the gas is continued. The mother-liquor separated from the crystals yields an additional quantity if again treated with cyanogen gas. The crystals are washed with a small quantity of alcohol, and dissolved in a hot mixture of ether and alcohol, into which solution cyanogen is again passed to transform any codeine that may have remained unacted on. Cyanocodeine then separates in thin, shining, colourless or faintly yellow, six-sided laminæ. It dissolves easily in boiling absolute alcohol, or in a mixture of alcohol and ether, sparingly in water, more easily on addition of alcohol; this solution however does not deposit anything when left at rest, and decomposes by evaporation, leaving a residue of codeine.

Cyanocodeine yields by analysis 68·13 per cent. C, 6·05 H, and 11·66 N, calculation requiring 68·37 per cent. C, 5·97 H, 11·68 N, and 13·97 O.

[It is perhaps a hydrocyanate of cyanocodeine, $C^{18}H^{20}CyNO^3.HCy$.]

With *hydrochloric acid*, it forms a crystallisable salt, which however quickly decomposes, giving off ammonia on addition of potash; the hydrochloric acid solution, if left to stand for twenty-four hours, gives off hydrocyanic acid. With *oxalic* and *sulphuric* acids, cyanocodeine forms sparingly soluble salts which likewise decompose quickly, giving off ammonia and hydrocyanic acid. (Anderson.)

Ethylcodeine, $C^{20}H^{25}NO^3 = C^{18}H^{20}(C^2H^5)NO^3$. (H. How, Chem. Soc. Qu. J. vi. 125.)—The hydriodate of this base is obtained by enclosing in a sealed tube pulverised codeine with a small quantity of iodide of ethyl and sufficient absolute alcohol to dissolve the codeine, and heating the mixture in the water-bath for two hours. On cooling, a crystalline mass is obtained, very soluble in cold water, whence it is deposited, after concentration, in tufts of fine needles. Dried at 100° C., it contains 52·59 per cent. C, 5·87 H, and 27·91 I, agreeing nearly with the formula $C^{20}H^{25}NO^3,HI$, which requires 52·73 C, 5·76 H, and 27·92 I.

The solution is not precipitated either by potash or by ammonia. Treated with oxide of silver, it yields a strongly alkaline liquid which absorbs carbonic acid during evaporation. The residue is again attacked by iodide of ethyl, but the reaction appears to be very complicated.

Iodocodeine, $C^{18}H^{21}NO^3.I^3$. (Anderson, *loc. cit.*)—This compound—which should rather be called iodide of codeine, for it is not a substitution-product—is prepared by dissolving equal weights of iodine and codeine in the smallest possible quantities of alcohol, mixing the solutions, and leaving the mixture at rest; iodocodeine is then deposited, after a longer or shorter time, according to the concentration of the solutions, in triangular plates belonging to the triclinic system; they have a fine ruby colour by transmitted light, deep violet by reflected light, and if well illuminated, exhibit a beautiful adamantine, nearly metallic lustre. They are insoluble in water and in ether, but dissolve in alcohol with red-brown colour. After drying in vacuo, they contain, according to the mean of Anderson's analyses, 32·07 per cent. C, 3·39 H, and 55·32 I, the formula requiring 31·75 C, 3·08 H, and 56 I.

Iodocodeine gives off iodine at 100° C. It is dissolved by hot sulphuric acid, and slowly attacked by hot nitric acid. Boiling potash dissolves out the iodine and leaves codeine. With sulphuretted hydrogen, it yields hydriodate of codeine, with deposition of sulphur. With nitrate of silver, it forms an immediate precipitate, which, however, contains only about $\frac{7}{8}$ of the iodine in the compound. (Anderson, *loc. cit.*)

Nitrocodeine, $C^{18}H^{20}N^2O^5 = C^{18}H^{20}(NO^2)NO^3$. (Anderson, *loc. cit.*)—To prepare this base, dilute nitric acid, of specific gravity 1·060, is heated in a flask to a temperature short of ebullition, finely pulverised codeine is added, and the mixture is kept at a gentle heat for a few minutes, till a sample of it gives a precipitate with ammonia, and the quantity of this precipitate no longer increases after several trials. The whole of the solution is then saturated with ammonia and briskly agitated, whereby a thick precipitate of nitrocodeine is formed. The action of the nitric acid is very rapid, the transformation being complete in a few minutes, so that close watching is necessary to seize the exact point at which the liquid should be saturated with ammonia. Evolution of red vapours is a sign that the action has gone too far, and that a portion of the codeine has been converted into a peculiar red substance, not yet examined. In this case, it is best to interrupt the process before the whole of the codeine is decomposed. Strong nitric acid acts on codeine with violence, producing a yellow resin.

Nitrocodeine precipitated by ammonia, as above, forms very small silvery laminæ, slightly tinged with yellow. It is purified from colouring matter and a little unaltered codeine, by solution in hydrochloric acid, boiling with animal charcoal, reprecipitation by ammonia, and recrystallisation from dilute alcohol or ether-alcohol. From alcohol it crystallises in thin silky laminæ of a pale tawny colour, forming, when dry, an interlaced silky mass. From ether-alcohol it separates, by evaporation, in small yellowish crystals, exhibiting under the microscope the form of quadrilateral prisms with dihedral summits. It is sparingly soluble in boiling water, and separates in small crystals on cooling. It dissolves readily in boiling alcohol, sparingly in ether. It gives by analysis 62·49—63·10 C, and 5·91—6·04 H, the formula requiring 62·79 C, and 5·81 H.

Nitrocodeine when cautiously heated melts to a yellow liquid, which solidifies to a highly crystalline mass. At a higher temperature, it decomposes quickly, without flame, leaving a bulky charcoal. When the alcoholic solution of nitrocodeine is treated with sulphide of ammonium at the heat of the water-bath, it acquires a dark colour and deposits sulphur. When the action is complete, the filtered liquid yields with ammonia a brown amorphous precipitate, which, after solution in hydrochloric acid, boiling with animal charcoal, and reprecipitation, forms a pale yellow basic substance (*azocodeine*), which has not been further examined.

Nitrocodeine dissolves in acids, forming salts which are neutral to test-papers, and from which the base is precipitated as a crystalline powder by potash or ammonia.

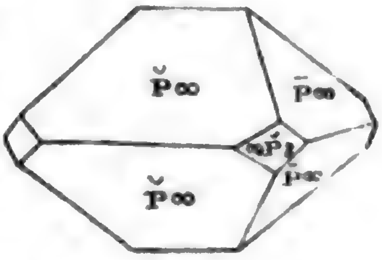
The *hydrochlorate* is obtained by evaporation in the form of an uncrystallisable resinous mass. The *chloroplatinate*, $C^{18}H^{20}(NO^2)NO^3.HCl.PtCl^2 + 2aq.$, is a yellow precipitate, insoluble in water and in alcohol. It gives off its water at 100° C., and then yields by analysis 17·88 per cent. Pt (calc. 17·93).

The *oxalate* crystallises in short yellow prisms, very soluble in water. The *sulphate*, $2C^{18}H^{20}(NO^2)NO^3.H^2SO^4 + 2aq.$ (at 100° C.), is obtained in radiate groups of short pointed needles, neutral to test-paper, and very soluble in boiling water.

COD-LIVER OIL. See OILS, ANIMAL.

CŒLESTIN. Sr^2SO^4 or $SrO.SO^3$.—Native sulphate of strontium. This mineral is so named from its occasional delicate blue colour; though it is frequently found of other shades, as white, greyish and yellowish-white, and red. It occurs massive, and crystallised, sometimes also in fibrous and stellated forms. It belongs to the trimetric system, being isomorphous with sulphate of barium and sulphate of calcium. The primary form is a rhombic prism of 104° 20′ and 75° 40′. An ordinary combination is $\bar{P}\infty$. $\breve{P}\infty$. $\infty\breve{P}2$ (*fig.* 128). Cleavage very distinct parallel to $\breve{P}\infty$; less distinct parallel to $\bar{P}\infty$. It has a vitreous lustre, and is transparent, translucent, or opaque. It is very brittle. Specific gravity 3·953 (Breithaupt). Hardness 3—3·5. Before the blowpipe it fuses to a white, opaque, friable enamel. Cœlestin occurs abundantly in the massive form at Montmartre, and near Bristol. The crystallised variety is found in the red sandstone at Inverness, and in many other localities. Splendid groups of crystals occur at Girgenti in Sicily, mixed with sulphur and gypsum. Fine specimens are also met with at Bex in Switzerland, Conil in Spain, Retzbanya in Hungary, in compact limestone near Lake Erie, and many other localities. Crystals of cœlestin are often found in which the strontium is partially replaced by barium or calcium, the substitution being attended with a certain alteration in the magnitude of the angles of the crystal. The blue colouring of certain specimens of cœlestin appears to be due to the presence of small quantities of ferroso-ferric phosphate. (Jahresber. f. Chem. 1847, 1219; 1849, 776; 1850, 757; 1853, 842; 1855, 970; 1856, 874; 1857, 692.—Dana, ii. 368.)

Fig. 128.



CŒLOCLINE POLYCARPA. The tree which yields the Abeocouta bark of West Africa, where it is used for colouring skins, mats, &c.; also as a local application for ulcers. According to Stenhouse, the bark contains berberine.

CŒRULIC ACID. According to Vlaanderen and Mulder (Jahresb. d. Chem. 1858, p. 262), caffeic or caffetannic acid (i. 709), which they regard as $C^{14}H^{16}O^7$, yields by oxidation, *caffeanic* acid, $C^{14}H^{16}O^8$, and from this, by the action of air and ammonia, are produced *α-cærulic* acid, $C^{14}H^{16}O^9$, and *β-cærulic* acid, $C^{14}H^{14}O^8$, both of which form blue salts, and consequently resemble viridic acid (*q. v.*)

CŒRULIN. A name sometimes applied to the body $C^8H^{15}NO$, supposed to exist in sulphindigotic acid, $C^8H^{15}NO.SO^3$.

COFFEE. *Café. Kaffee.*—Coffee beans are the seed of *Caffea arabica*, a tree of the rubiaceous order, indigenous in southern Abyssinia. It is said to have been transplanted into Arabia at the beginning of the fifteenth century, and the cultivation has since been extended to the West Indies, Brazil, Java, Ceylon, and other warm countries. The seeds are separated from the soft pods by bruising with a heavy roller, then washed and dried, and lastly freed from their parchment-like coating by passing them under a wooden edge-wheel, and subsequently winnowing. In this state they are sent to Europe.

The most highly esteemed variety is the Mocha coffee, which is grown in the province of Yemen in Arabia: it has a more agreeable taste and smell than any other kind, and is distinguished by its yellow colour and the comparative smallness and roundness of the bean. Next to it in European reputation, are the Martinique and Bourbon coffees; the former is larger than the Arabian and more oblong; it is rounded at the ends, of greenish colour, and almost always retains a silver-grey pellicle which comes off in roasting. The Bourbon coffee approaches nearest to the Mocha, from which it originally sprung. The Saint Domingo coffee, which has its two extremities pointed, is much less esteemed than the preceding.

The chemical properties and composition of coffee beans have been made the subject of numerous investigations. Schroeder in 1808 (Gehler's J. Chem. Phys. vi. 564), showed that they contain fat, resin, mucus, extractive matter, &c., and that the aqueous extract is coloured green by ferroso-ferric salts, and yields a green precipitate with copper-salts on addition of an alkali.—Runge in 1820 (*Materalien zur Physiologie*, Lief i. p. 146) discovered caffeine: and Pfaff (*Syst. d. Materia Medica*, iii. 3) found in the beans, in addition to this substance, two acids, viz. caffeic and caffetannic acids, which, however, were afterwards shown by Rochleder to be identical. The examination of coffee-beans was further carried out by Robiquet and Boutron (J. Pharm. xxiii. 101), who found, in addition to fat, extractive matter, and caffeine, a white crystallisable substance, and an acid precipitable by neutral acetate of lead;—by Rochleder (Ann. Ch. Pharm. l. 224; lix, 300; lxiii. 193; lxvi. 35), who found legumin, and a very small quantity of citric acid (a few grains in a pound of coffee);—afterwards by Payen (Ann. Ch. Phys. [3] xxvi. 108), von Bibra (*Narkotische Genussmittel*, u. s. w. Nürnberg, 1855), and lastly by Graham, Stenhouse, and Campbell (Chem. Soc. Qu. J. ix. 33). According to Payen, the caffeine exists partly in the free state, partly as caffetannate of caffeine and potassium (a view considered as doubtful by Graham, Stenhouse, and Campbell). Payen also found sugar in the unroasted beans. According to Graham, Stenhouse, and Campbell, the unroasted beans contain, partly cane-sugar, partly another kind of sugar, probably in combination as a glucoside, the total amount of sugar in various kinds of coffee varying from 6·0 to 7·5 per cent. The caffeine amounts to 1·0 per cent. according to Payen; from 0·5 to 1·0 according to Graham, Stenhouse, and Campbell. The amount of fat appears to vary considerably. According to Rochleder, the beans contain olein and palmitin, perhaps also laurostearin. Robiquet and Boutron found in 8 pts. of Martinique coffee, 1 pt. of fat. Payen found that Mocha coffee contains about 13 per cent. of fat, which is rather greater than the proportion in Martinique coffee. The fat of Mocha coffee also retains the odoriferous principle more tenaciously than that of other varieties; it is yellowish, very fluid, and separates only into two portions of different melting points, whereas that of Martinique coffee has a more brownish colour, is less fluid, and may be separated into at least four distinct fats, melting at about 5°, 20°, 50°, and 90° C. respectively, the last being a kind of vegetable wax. According to Stenhouse, coffee beans contain about 12 per cent. of fat. According to Vogel, benzene extracts from them 18 per cent. of soluble matter.

The following is the average composition of raw coffee beans, as determined by Payen and von Bibra:—

	Payen.		v. Bibra.
Cellulose	34	Woody fibre	36 to 59
Water	12	Water	5 to 9
Fat	10 to 13	Fats	3 to 5
Glucose, dextrin, and organic acid	15·5	Sugar	6 to 7
Legumin and Casein	10	Vegetable casein	undetermined
Other nitrogenous substances	3		
Caffeine (free)	0·8	Caffeine	0·2 to 0·8
Caffetannate of caffeine and potassium	3·5 to 5·0	Essential oil	not weighable
Viscid essential oil (insoluble in water)	0·001	Substances precipitable by neutral acetate of lead	7 to 8
Aromatic oils, some lighter, others heavier than water	0·002	Precipitable by basic acetate of lead	5 to 6
Ash	6·7	Ash	6 to 7

Levi (Ann. Ch. Pharm. l. 421) found 3·2 per cent. ash.—**T. J. Herapath** (Chem. Gaz. 1848, p. 159) found 6·7 per cent. in the dry beans. Vogel found 3·5 per cent. ash, of which 0·80 was soluble in water.

Composition of the Ash of Coffee-beans in 100 *parts.*

			Graham, Stenhouse, and Campbell.						
	Levi.	Herapath.	Ceylon cult.	Ceylon wild.	Java.	Costa Rica.	Jamaica.	Mocha.	Neil-gherry.
Potash . . .	50·9	16·5	55·1	52·7	54·0	53·2	53·7	51·6	55·8
Soda	14·8	7·1							
Lime	4·8	27·7	4·1	4·6	4·1	4·6	6·1	5·9	6·7
Magnesia . .	10·9	5·9	8·2	8·5	8·2	8·7	8·4	8·9	8·5
Ferric oxide .	0·6		0·45	0·98	0·73	0·63	0·44	0·44	0·61
Sulphuric acid anhydrous .	trace.	1·3	3·6	4·5	3·5	3·8	3·1	5·2	3·1
Carbonic acid anhydrous .	—	—	17·5	16·9	18·1	16·9	16·4	17·0	14·9
Phosphoric acid anhydrous	13·6	40·7	10·3	11·6	11·0	10·8	11·1	10·1	10·8
Chlorine . . .	1·2	0·4	1·1	0·5	0·8	1·0	0·7	0·6	0·6
Silica	3·6	0·4							

From the analysis of the six varieties by Graham, Stenhouse, and Campbell, which exhibit a remarkably close agreement, it appears that coffee-ash is especially distinguished by the absence of soda and silica. The soda found by Levi is doubtful, and Herapath's results, which differ enormously from all the rest, may be rejected as untrustworthy.

Roasting Coffee.—Coffee-beans, when heated or roasted, assume a light brown, chestnut-brown, or even black colour, according to the degree of heat applied. The air-dried beans diminish in weight during roasting by 15 or 25 per cent., but increase considerably in volume, the increase amounting, according to v. Bibra, to from 50 to 58 per cent., if they have been previously washed, or if they are strongly heated. According to Payen, 100 grms. of raw coffee-beans yield 50 grms. of roasted beans, and 100 vols. of the beans increase by roasting to 130 vols. To roast the beans with perfect regularity, it is best to steep them in water for ten or twelve minutes, then to dry them lightly, after draining, and roast them immediately. The steeping removes impurities, and perhaps also serves to impart to the beans a uniform amount of water, so that they get more regularly heated.

The vessels used for roasting coffee are generally of iron: recently silver and glass vessels have also been used for the purpose. The chief point to be attended to in their construction and use, is to ensure that the heat be gradual and not too strong. If the beans are heated above the temperature required to brown them, they swell up strongly, turn black, and ultimately become carbonised. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 794.)

By heating coffee-beans in a retort with proper condensing apparatus, the following volatile products are successively obtained (v. Bibra):

1. A volatile oil, pre-existing in the raw beans, and little, or not at all altered by heat.
2. Volatile oil having the odour of roasted coffee.
3. Empyreumatic oil.
4. A fatty body.
5. Acetic acid.
6. A small quantity of caffeine, together with an aromatic body, probably assamar (i. 428).
7. Humoïd substances, and one or more compounds which easily reduce gold and silver-salts.

The statement of Rochleder that pyrocatechin is formed in the distillation (from the caffetannic acid), is not confirmed by the observations of Graham, Stenhouse, and Campbell.

The composition of roasted coffee has been investigated by Payen, by v. Bibra, and by Graham, Stenhouse, and Campbell. Payen exhausted 100 grms. of ground coffee with a litre of boiling water; heated the filtrate in a distillatory apparatus for two hours, by which time it had quite lost its odour; and collected the distillate in four connected receivers, the first of which gradually became heated to about 90° C., while the second was kept between 25° and 30°, and the third and fourth were cooled to 0°, or a little below, the vapours which escaped from the fourth being passed through strong sulphuric acid, or through a tube filled with red-hot oxide of copper.

In the first receiver, a yellowish water collected, and a few drops of oil, amounting to about $\frac{1}{10}$ of the infusion, floated on the surface, quite destitute of fragrance. The liquid condensed in the second receiver amounted to about $\frac{1}{100}$ of the volume of the infusion: a few drops of an odourless fixed oil floated on the top of the watery liquid, which possessed the fragrant odour of coffee in so high a degree that a few drops of it sufficed to impart the odour to a cup of milk. The water of this second receiver contained the principal part of the coffee-aroma, concentrated about 100 times. On agitating the water with about $\frac{1}{3}$ of its volume of ether, repeating this treatment several times, and then evaporating the ether, there remained a yellowish oil (about 0·1 grm. from 10 grms.), the very strong odour of which resembled that of the aroma common to the several varieties of coffee. Another oil, somewhat more volatile, and of more delicate aromatic odour, remained, together with a little ether, in the water: this oil appears to be contained especially in the finer kinds of coffee, as that of Mocha.

To obtain the whole of the oils from the infusion of coffee, lumps of chloride of calcium are introduced into the first two receivers during the distillation; the third receiver is connected with a chloride-of-calcium-tube and cooled to + 20° C. A solution of chloride of calcium is then obtained, containing the whole of the volatile coffee-oil, which may be extracted from it by agitation with ether. Payen obtained from 10,000 pts. of coffee only 2 pts. of this oil, but possessing so strong an odour that a single drop sufficed to fill a whole room with the characteristic odour of coffee.

If the third receiver be cooled to − 2° or − 3° C. during the distillation, a few drops of liquid collect in it having the odour of coffee, but likewise the less agreeable odour of empyreumatic hydrocarbons, which are present in greater quantity in proportion as the coffee has been more strongly roasted. The odour of these bodies is perceptible also in the fourth receiver and in the vapours which escape therefrom, these vapours likewise imparting a brown colour to oil of vitriol.

According to Zenneck, the aroma of coffee is obtained in larger quantity by adding sulphuric acid to the liquid in the retort.

Von Bibra, by exhausting roasted coffee-beans with ether, obtained from Mocha coffee 8·8 to 9·3 per cent. fatty matter; from Java coffee 8·9 to 9·2 per cent. He supposes that this fat is for the most part produced during the roasting, inasmuch as the raw beans yielded only from 4 to 5 per cent. of fat; and, if the beans thus exhausted were subsequently roasted, they yielded an additional 4 to 6 per cent. fat on being again treated with ether. It is possible, however, that the fat in the raw bean is enclosed in cells, and does not become accessible to the ether till the envelopes are burst by the heat.

The fat extracted by ether has the consistence of cacao-butter (i. 699), and exhales the peculiar aroma of coffee, which appears to be produced from the volatile oil of the raw beans by roasting; by boiling the fat with water this aroma is driven off. The fat is a mixture of several substances, some of which are likewise soluble in alcohol. It appears to contain olein and palmitin, together with a resin and a hydrocarbon; perhaps also other bodies. The ethereal extract likewise contains the whole of the caffeine, and a body which colours iron-salts greenish, precipitates lead-salts, and reduces gold and silver-salts.

When ground coffee which has been exhausted with ether, is twice heated with boiling water, after drying, a dark brown, strongly acid liquid is obtained, having a very bitter taste, but without the peculiar agreeable flavour of coffee. The aqueous extract likewise contains sugar, humoïd substances, assamar, and tannic acid, nearly identical with caffetannic acid; also a substance which reduces gold- and silver-salts, a small quantity of empyreumatic oil, salts, and indifferent substances insoluble in alcohol. The brown bitter products in roasted coffee appear to be produced chiefly from the sugar, inasmuch as that substance diminishes greatly in quantity, or disappears altogether, in the roasting process. Graham, Stenhouse and Campbell found that, whilst the raw beans contained 5·7 to 7·8 per cent. sugar, the roasted beans never contained more than 1·1 per cent., and in many instances none at all.

The residue, after extraction with ether and water, yielded by boiling with water containing carbonate of sodium, a solution coloured deep brown by humoïd substances.

Decoction of coffee does not contain albumin or legumin.

Graham, Stenhouse, and Campbell found in roasted coffee, a brown volatile oil (the *caffeone* of Boutron and Frémy), heavier than water, easily soluble in ether, sparingly in boiling water, but communicating to the water a strong aromatic odour. They also found from 2·5 to 3·0 per cent. nitrogen and sometimes a little sugar.

Von Bibra finds that when ground coffee is treated with boiling water in a French coffee-machine,—in which the boiling water is forced by the pressure of its own vapour from the lower vessel into the upper, which contains the coffee,—from 10 to 12 pts. out of 100 of the coffee pass into the solution: by complete exhaustion, a larger proportion would of course be dissolved. The proportion of soluble matter is increased, up to a certain point, by strong roasting. According to Cadet, coffee roasted to a red-brown colour yields 12·3 per cent.; chestnut-brown coffee 18·5 per cent.; and dark brown 23·7 per cent. of soluble constituents. Payen obtained 37 per cent., and the residue, after thorough exhaustion with water, yielded only 1·2 per cent. ash, ⅓ of which consisted of soluble salts. Lehmann found in roasted Java coffee, 21·5 per cent. soluble matter. Vogel found 39 per cent. (in the raw beans only 25 per cent.). Soft water dissolves out more than hard water; water containing carbonate of soda most of all.

The aqueous extract of coffee yields 16·6 per cent. ash, containing 51·5 per cent. K^2O, 3·6 Ca^2O, 8·6 Mg^2O, 0·2 Fe^4O^3, 10·0 P^2O^5, 40·0 SO^3, 20·5 CO^2, 2·0 KCl, 0·7 SiO^2, with 0·5 sand and charcoal.

Physiological action.—Coffee acts physiologically in two ways: first, by stimulating the action of the nervous and vascular systems, thereby producing a feeling of cheerfulness and mental activity; secondly, by retarding the transformation of tissue, and thus, to a certain extent, supplying the place of other nutriment. Experience has in fact shown that labourers who habitually take coffee as a beverage, require less nitrogenous food to keep up their strength than those who do not take coffee. The stimulating and invigorating action of coffee appears to depend both upon the empyreumatic oil and the caffeine; the retardation of tissue-transformation, chiefly on the empyreumatic oil, the caffeine acting in this manner only when it is present in considerable quantity. The unpleasant symptoms which sometimes attend an excessive use of coffee, such as headache, trembling, and a peculiar delirious sensation, are mainly due to the caffeine (J. Lehmann, Ann. Ch. Pharm. lxxxvii. 207). The assamar and tannic acid in roasted coffee doubtless also contribute in some way to its physiological action.

Tea resembles coffee in containing theine (identical with caffeine) and tannic acid; and, accordingly, its action resembles that of coffee to a certain extent; it differs from coffee, however in not containing the peculiar empyreumatic oils just mentioned, and in being richer in theine and tannin.

Adulteration of Coffee. (Graham, Stenhouse, and Campbell, *loc. cit.*)—Various substances, more or less resembling coffee, are used, either as substitutes for, or additions to it. A great variety of seeds were tried in France during the continuance of the continental blockade, including—in addition to maize, barley, oats, and the other cereals—the seeds of the yellow flag (*Iris pseudo-acorus*), the grey or chick pea (*Cicer arietinum*), the milk vetch or Andalusian astragalus (*Astragalus boeticus*), the *Hibiscus esculentus*, the holly, Spanish broom, acorns, chestnuts, the small lupine (*Lupinus augustifolia*), peas, haricots, horse-beans, sunflower, pips of the gooseberry and grape eglantine (*Rosa villosa*), and the capsules of box (*Buxus sempervirens*). Of these the yellow flag, a common marsh-plant in England, appears to offer the greatest similarity to coffee; but it is doubtful whether the resemblance extends beyond the aroma of the seed when roasted. Indeed no seed appears to be known which, when roasted and pulverised, forms a true and efficient substitute for coffee, either in the physiological properties or in the chemical composition of the soluble extract. The poorer sorts of coffee-beans are sometimes tinted by dusting them with coloured powders, such as Prussian blue, powder of lime-tree charcoal, green earth, &c., mixed with a little graphite, to give them the silvery appearance of the finer sorts.

The use of certain roots roasted and pulverised, to mix with ground coffee, is, however, much more common. The roots most used for this purpose are those of chicory (*Cichorium intybus*), carrot, beet, rush-nut (*Cyperus esculentus*), earth-nut (*Arachis hypogæa*), scratch-weed (*Galium aparine*), fern (*Polypodium filix mas*), and butcher's-broom (*Ruscus aculeatus*).

These roots are prepared by cutting them into thin slices, drying them on a stove, and then passing them through a coffee-roaster, generally with addition of about 2 per cent. of butter, and sometimes of a red powder, to give them the colour of coffee. In this country and in France, the root most used as an addition to coffee is chicory, the annual consumption of which in France amounts to 6,000,000 kilogrammes. In Germany, beet and carrot are extensively used for the same purpose. Not one of these roots contains either caffeine or the peculiar aromatic oils of roasted coffee, and hence they can never serve as efficient substitutes for coffee; but they are valued as an addition to it, because they contain a large quantity of sugar—chicory as much as 30 per cent.—and consequently, when roasted, acquire the peculiar bitter taste and somewhat of the aroma of caramel or burnt sugar, which is well known to be one of the strongest and most general of our gustatory preferences, being that which gives the peculiar flavour to the several varieties of brown beer or porter (i. 529).

The examination of a sample of ground coffee for the detection and estimation of these admixtures, is a matter of some difficulty. As none of the roots contain caffeine, the quantitative determination of that base in the sample may give an approximation to its degree of purity. For this purpose, the coffee may be exhausted by repeated boiling with hot water; the solution concentrated a little by evaporation; the caffetannic acid, and certain other substances, precipitated first by neutral and then by basic acetate of lead; the excess of lead removed from the filtrate by sulphuretted hydrogen; the liquid then evaporated to dryness; the dry matter exhausted with spirit of specific gravity 0·840; and the alcoholic solution concentrated to a nearly syrupy state, and left to stand for ten days. The crystals of caffeine, which then separate, are collected on a small filter, compressed powerfully to remove the mother-liquor, then redissolved in a small quantity of water, and the solution is evaporated and crystallised anew. It yields almost pure caffeine, the quantity of which in the sample is thus determined. Samples of pure coffee of several varieties yielded, by this treatment, from 0·80 to 1·01 per cent. caffeine; if then the amount obtained from a given sample be less than 0·80, the admixture of some other substance may be inferred. (Graham, Stenhouse, and Campbell.)

If it be desired merely to determine whether a given sample of ground vegetable substance contains coffee or not, the search for caffeine may be made by a simpler process, namely, by evaporating the aqueous infusion to dryness after addition of lime, treating the dry mass with ether, leaving the solution to crystallise by evaporation, and testing the crystals with nitric acid and ammonia, whereby, if caffeine be present, the purple colour of murexid is produced (i. 708).

The formation of quinone by the oxidation of caffetannic acid (i. 709), may also be used as a means of recognising the presence of coffee in a mixture. For this purpose the infusion of the powder is evaporated to syrup, and 1 pt. of the residue is distilled with 4 pts. peroxide of manganese, and 1 pt. oil of vitriol diluted with 1 vol. water; quinone is then given off, part subliming in crystals, while the rest passes over with the watery distillate. (Graham, Stenhouse, and Campbell.)

The adulterations of coffee are most easily detected by their physical characters, by the proportion of sugar contained in the sample, and by the composition of the ash.

1. *Action of Water.*—When hot water is applied to the powder of chicory and other roots, it softens immediately, from the facility with which the water is imbibed; whereas the grains of coffee remain hard and gritty. Roasted grain, such as wheat and barley, gives with hot water a thick mucilaginous infusion, while the infusion of coffee is remarkably thin and limpid. The grain-infusion generally contains starch, and gives a blue coloration with iodine, whereas the infusions of both coffee and chicory appear to be quite destitute of starch.

2. *Colouring Power.*—Chicory and the allied roots impart to water a much deeper colour than coffee, the coloration being also much more rapidly produced. By infusing equal quantities of the several substances with boiling water, and observing the colour of the filtered infusions in glass tubes of equal diameter, it was found:—if the colouring power of caramel be represented by 1000, that of chicory is 450, of maize 350, of dandelion-root 300·3, of red beet 300·3, of bread-raspings 274·72, of acorns 200, of highly-roasted coffee 173·31, of medium-roasted coffee 143·88, of peas 73·18, and of brown malt 25. Hence it appears that chicory has more than three times the colouring power of highly-roasted coffee; maize double that of coffee; whereas peas and beans have only about half the colouring power of coffee.

In infusions prepared with cold water, chicory exhibits four times the colouring power of coffee. If a few grains of roasted chicory or any other sweet root be dropped into a glass of cold water, without being stirred, a yellowish-brown colour diffuses rapidly through the liquid, whereas pure coffee gives no sensible colour to the water under similar circumstances.

3. *Specific Gravity of the Infusions.*—Coffee is sharply distinguished from the two most important classes of adulterating substances, the roots and cereals, by the comparatively low specific gravity of its infusion. The comparison may be made by dissolving 1 pt. of the substance in 10 pts. of cold water, raising the temperature to the boiling point, keeping it there for about half a minute, and then filtering. The leguminous seeds give infusions of low specific gravity: peas 1007·3, beans 1008·4. The specific gravity of coffee infusions varies from 1008·0, for Mocha, to 1009·5, that of Costa Rica coffee; that of chicory infusion is much higher, ranging in different samples from 1019·1 to 1023·2. Infusions of cereals stand equally high, or higher, in the scale of gravity, rye-meal giving 1021·6, and maize 1021·5.

4. *Action of Ether.*—The following substances, agitated with ten times their weight of ether, give different proportions of matter soluble in that liquid, viz.:

Roasted beans	1·81	per cent. of oil and resin,
,, maize	5·15	,, ,, ,,
,, chicory (Yorkshire) . .	6·83	,, ,, ,,
,, coffee (Mocha) . .	15·93	,, ,, ,,

the last including probably 1 per cent. of caffeine. Hence it appears that coffee yields to ether much more soluble matter than beans, maize, or chicory, which represent the three classes of leguminous seeds, cereals, and sweet roots. The fat obtained from chicory was doubtless that which is added in the roasting process, to prevent burning. The experiment with ether is easily made, and may sometimes prove valuable.

5. *Quantity of fermentable Sugar.*—The quantity of fermentable sugar in sweet roots, both before and after torrefaction, is much greater than in coffee. By subjecting the different substances to fermentation with yeast, and determining the amount of alcohol in the distillate (see SUGAR), the sugar in raw coffee is found to vary from 6·20 to 7·52 per cent.; that of roasted coffee from 0·0 to 1·14. The proportion in chicory and other sweet roots is given in the following table:

	Sugar per cent.	
	Raw.	Roasted.
Foreign chicory	23·76	11·98
Guernsey „	30·49	15·96
English „	35·23	17·98
„ „ (Yorkshire)	32·06	9·86
Mangold-wurzel	23·68	9·96
Carrots (ordinary)	31·98	11·53
Turnips	30·48	9·65
Beetroot (red)	24·06	17·24
Dandelion root	21·96	9·08
Parsnips	21·70	6·98
Bonka (a coffee substitute)	—	5·82

These numbers are sufficient to show that the fermentation-test affords an easy method of distinguishing these roots from coffee. The leguminous seeds, cereals, and other seeds are not so easily distinguished by this method, the proportion of sugar in the roasted material varying only from 0·74 in lupine seed to 2·70 in acorns.

6. *Composition of the Ash.*—Coffee is remarkably distinguished from the roots and cereals by the small quantity of silica in its ash, which never exceeds 0·5 per cent.; and even this small quantity, which is not always present, probably arises from accidental adhesion of sand to the beans. Chicory-ash, on the other hand, contains (after deducting sand) from 3·81 to 10·52 per cent. silica (i. 962), and roasted dandelion-root 11·26 per cent. The proportion of silica may be determined, without making a formal analysis of the ash, by simply digesting it in strong hydrochloric acid and weighing the residue. In lupines, acorns, maize, and parsnips, the proportion of silica is not large enough to afford a good distinction from coffee; but lupine-ash contains 17·75 per cent. of soda, which, according to Graham, Stenhouse, and Campbell, is not found in coffee-ash; the ashes of lupines and of acorns likewise contain twice as much chlorine as coffee-ash, and in the ash of maize the proportion of phosphoric acid is very high, viz. 44·5 per cent., whereas in coffee-ash it is only about ten per cent. Beetroot ash is distinguished from coffee-ash by its very large amount of chlorine, which varies from about 8 to 29 per cent.

7. *Proportion of Nitrogen.*—The nitrogen in foreign raw chicory amounts to 1·51 per cent. in the roasted root to 1·42 per cent. English chicory gave, in the raw state 1·86, in the roasted state 1·74 per cent. nitrogen. In roasted coffee the proportion of nitrogen is rather greater, viz. about 2·75 per cent.; but the difference is not great enough to afford a good mode of distinction. It may, however, be admitted that less than 2 per cent. of nitrogen in coffee is a strong presumption of adulteration with chicory or some other root.

On the whole, we may conclude that the best indication-tests of the presence of foreign substances in ground coffee are afforded by the colouring power, the specific gravity of the infusion, the fermentation-test, and the composition of the ash.

COFFEE LEAVES. The leaves of the coffee tree have been examined by Stenhouse (Phil. Mag. [4] vii. 21), who received a sample of them, dried at rather too high a temperature, from Sumatra. They were found to contain 1·2 per cent. caffeine, and altogether 2·1 per cent. nitrogen; as some of the caffeine may have been decomposed in the drying of the leaves, the real proportion may perhaps amount to 1·5 per cent. They also appear to contain a larger proportion of caffetannic acid than the beans; the proportion of matter extracted by water was 38·8 per cent. An infusion of the leaves in boiling water has a deep brown colour, and in taste and odour resembles a mixture of tea and coffee. The leaves might therefore, perhaps, be used as a substitute for tea-leaves or coffee-beans. Their use for this purpose was first suggested by Van den Corput in Brussels. (Ann. Ch. Pharm. lxxxix. 244.)

COFFEINE. Syn. with CAFFEINE (i. 707).

COGNAC. The finest kind of French brandy distilled from wine; it takes its name from the town of Cognac, in the Département de la Charente. (See BRANDY, i. 652.)

COHOBATION. The continuous redistillation of the same liquid from the same materials.

COHESION and **ADHESION.** Cohesion is the force by which particles of one and the same body, or homogenous particles in general, are held together. Adhesion that which holds together the particles of two dissimilar bodies when brought into close contact.

These forces appear to act only at distances inappreciable to our senses. When a solid body, as a piece of wood or stone, is broken, the pieces cannot be made to cohere again by merely pressing them together, because the surfaces, being uneven, can only come into contact at a few points, and the cohesive force is imperceptible; but if the bodies touch each other by large flat surfaces, as when two well polished plates of glass or metal are pressed together, they cohere with great force.

The adhesion between the particles of dissimilar bodies is determined by precisely similar conditions. Plates of lead and tin, or of copper and silver, may be almost inseparably united by strong pressure between rollers. Adhesion takes place with peculiar facility when one or both of the bodies is in the liquid state, because the particles, being free to move, can easily adapt themselves to each other. All liquids, like oil and water, which do not mix, adhere with more or less force by their surfaces, and adhesion shows itself in most cases when a liquid comes in contact with a solid body, the liquid being then said to wet the solid. A glass plate suspended from the arm of a balance and made to touch the surface of water requires considerable force to separate it. If the liquid which adheres to the surface of the solid afterwards solidifies, the adhesion becomes still stronger: this is the principle of cementing. When two glass plates are joined together with sealing wax, the adhesion is sometimes so strong that in attempting to part them, particles of the glass separate from each other rather than from the wax.

Notwithstanding the great difference which appears to exist between these molecular forces, and that of gravitation, the former acting only at insensible, while the latter acts at all distances, it is not difficult to show that both kinds of attraction may be merely different modifications of the same power. Let it be assumed that all ultimate atoms attract one another with forces varying directly as their masses and inversely as the squares of the distances between them, and that the aggregates of atoms constituting the physical molecules are not spherical, at least not in all cases. The law of molecular attraction will then depend in great part on the forms and dimensions of these molecules. The attraction between spheres composed of particles which attract one another according to the law of the inverse squares, is the same as if the whole matter of each sphere were concentrated in its centre, that is to say, the spheres attract one another inversely as the square of the distance between their centres. But in bodies of any other shape, the attraction may be regarded as consisting of two parts, one following the law of the inverse squares, just as if the bodies were spherical, the other dependent on the shape of the bodies, and varying inversely as the cube of the distance between their centres of gravity. Such is the case with the attraction of the earth and moon. The equatorial protuberance of the earth produces certain perturbations in the relative movement of the two bodies, which vary in magnitude, according to the law last stated, and would become much more perceptible if the earth and moon were nearer to each other, but would vanish if the distance between them were much greater than it is: for example, if the distance were diminished to $\frac{1}{10}$ of its present amount, the principal part of the attractive force, which determines the elliptical motion, would be increased 100 times, but the disturbing force depending on the figure would be increased 1000 times. If then the law of attraction between the molecules of bodies be affected in like manner by their figures, it will follow that at the extremely small distances existing between the particles of a solid body or of two bodies pressed closely together, the molecular force, which determines the phenomena of cohesion and adhesion, may become almost immeasurably greater than when they are separated by any appreciable distance: for the molecules are so minute that the smallest distance appreciable to our senses may be regarded as infinitely great compared with their dimensions, so that it is only at insensible distances that the influence of their form makes itself felt.

The force of cohesion varies with the temperature and the nature of the body. In gases, in which the dimensions of the actual material particles must be supposed to be infinitely small as compared with the intervals between them, the cohesive force is little, if at all perceptible; in fact, the particles of gases have a constant tendency to fly asunder. (See GASES and HEAT.)

In **liquids**, the distance between the particles is still sufficiently great, compared with their size, to give great freedom of motion, but not sufficient to render the molecular attraction depending on the form of the particles imperceptible; hence liquids, though their particles yield with ease to any external force, nevertheless exhibit, when left to themselves, a tendency to assume the spherical form, that being the arrangement in which a given number of particles occupy the smallest space; since, however, the liquid mass is subject to the influence of other forces, as gravitation and adhesion, the spherical form of a drop is never perfect; this may be seen in the form which drops of mercury assume on glass, or water on glass smeared with fat or lycopodium. As the temperature rises, the cohesive force becomes less, in consequence of the greater separation of the particles; consequently a heated liquid generally forms smaller drops than a cold one. Different liquids exhibit different degrees of cohesion, the cohesive power being very nearly proportional to the density.

In **solids**, the cohesive power shows itself in the highest degree, the particles not being able to move freely over one another, so that an external force, if it does not produce disruption, gives rise to an equal and parallel motion throughout the mass.

The force of cohesion in a solid is measured by the resistance which the body offers to any mechanical force tending to separate the particles. The resistance offered to a force tending to pull the particles asunder is called the **absolute cohesion** or **tenacity**; the lateral resistance to fracture is the **relative tenacity**; and the resistance which the body opposes to a crushing force is sometimes called the **retroactive tenacity** (*rückwirkende Festigkeit*). These three modifications of the cohesive strength have all been made the subject of direct experiment in numerous bodies; they are connected with each other by relations which are capable of exact mathematical analysis, but the investigation of which is foreign to the character of this work.

Absolute tenacity—Muschenbroeck made numerous experiments on the absolute tenacity of bodies; his results are given in the following table, which shows the weights required to break rods or wires of various materials when suspended from them:—

Absolute Tenacities of Solids

	Horizontal section = ¼ square line.	Horizontal section = ¼ sq. centimetre.
Elm-wood	87 pounds	918 kilogr.
Pine (*Pinus silvestris*)	97 „	1021 „
Fir (*Pinus abies*)	57—88 „	600—929 „
Oak	110—140 „	1150—1466 „
Beech	136—148 „	1349—1586 „
Ebony	89 „	934 „
Copper wire	266 „	2782 „
Brass	340 „	3550 „
Gold	442 „	4645 „
Lead	26 „	272 „
Tin	43 „	457 „
Silver	326 „	3411 „
Iron	398 „	4182 „
Glass (white)	14—22 „	142—233 „
Hempen cord	34—60 „	350—360 „

The great variation in the strength of hempen cord arises from the unequal quality of the fibre. Thin cords are comparatively stronger than thick ones, because they are made of better hemp.

The number for gold in the above table is doubtless too high. According to Count Sickingen, the tenacities of different metals are to one another in the following proportions:—

Gold	150955	Copper	304696
Silver	190771	Soft iron (Swedish)	362927
Platinum	262361	Hard iron	559880

The following table exhibits the absolute tenacities of different metals at the temperatures of 0°, 100°, and 200° C., as determined by Baudrimont (Ann. Ch. Phys. [3] xxx. 304.) The upper number opposite each metal gives the highest tenacity observed; the lower number the mean of each set of experiments:

Metals.	Tenacity in grammes for a transverse section of 1 mm. at		
	0°	100°	200°
Gold	19051	15766	13094
	18400	15224	12878
Platinum	23026	20421	18118
	22625	19284	17277
Copper	25338	22050	19839
	25100	21873	18215
Silver	28620	24526	18705
	28324	23266	18577
Palladium	36983	32871	29212
	36481	32484	27077
Iron	209813	201039	213305
	205405	191725	210270

These numbers show that the tenacity diminishes for the most part as the temperature rises; iron, however, exhibits an exception, being more tenacious at 200° than at 100° C.

Resistance to crushing.—The following table is the result of experiments by George Rennie, jun., published in the first part of the *Philosophical Transactions* for 1818.

Mr. Rennie found a cubic inch of the following bodies crushed by the following weights:—

	Crushing weight in lbs. av.
Elm	1284
American pine	1606
White deal	1928
English oak	3860
A prism of Portland stone, 2 inches long	805
Ditto statuary marble	3216
Craigleith stone	8688

Cubes of 1½ inch.

	Sp. gr.	
Chalk	—	1127
Brick of a pale red colour	2·085	1265
Roe-stone, Gloucestershire	—	1449
Red brick, mean of two trials	2·168	1817
Yellow-face baked Hammersmith paviors, three times	—	2254
Burnt ditto, mean of two trials	—	3243
Stourbridge, or fire brick	—	3864
Derby grit, a red friable sandstone	2·316	7070
Derby grit from another quarry	2·428	9776
Killala white freestone, not stratified	2·423	10264
Portland	2·428	10284
Craighleith white freestone	2·452	12346
Yorkshire paving, with the strata	2·507	12856
Ditto, against the strata	2·507	12856
White statuary marble, not veined	1·760	23632
Bramley-Fall sandstone, near Leeds, with strata	2·506	13632
Ditto, against strata	2·506	13632
Cornish granite	2·662	14302
Dundee sandstone, or breccia, two kinds	2·650	14918
A two inch cube of Portland	2·423	14918
Craighleith, with strata	2·452	15560
Devonshire red marble, variegated	—	16712
Compact limestone	2·584	17354
Peterhead granite, hard close-grained	—	18636
Black compact limestone, Limerick	2·598	19924
Purbeck	2·599	20610
Black Brabant marble	2·697	20742

Cubes of 1½ inch (continued).

	Sp. gr.	Crushing weight in lbs. av.
Very hard freestone	2·528	21254
White Italian veined marble	2·725	21783
Aberdeen granite, blue kind	2·625	24556

Cubes of different metals of ¼ inch were crushed by the following weights: —

	lbs. av.
Cast iron	9773
Cast copper	7318
Fine yellow brass	10304
Wrought-copper	6440
Cast tin	966
Cast lead	483

Bars of different metals, 6 inches long, and ¼ of an inch square, were suspended by nippers, and broken by the following weights: —

	lbs. av.
Cast iron, horizontal	1166
Ditto, vertical	1218
Cast steel, previously tilted	8391
Blistered steel, reduced by the hammer	8322
Shear steel, ditto	7977
Swedish iron, ditto	4504
English iron, ditto	3492
Hard gun-metal, mean of two trials	2273
Wrought copper, reduced by hammer	2112
Cast copper	1192
Fine yellow brass	1123
Cast tin	296
Cast lead	114

On the tenacity and other mechanical properties of *cast iron*, a large number of experiments were made by Stephenson, Fairbairn, and Hodgkinson, in connection with the construction of tubular bridges (*The Britannia and Conway Tubular Bridges*, by Clarke, London, 1850; Ann. Min. [4] xx. 427). The experiments on the resistance to direct tension, gave for the absolute tenacity of cast-iron a mean value of 10 to 11 kilogrammes for a square millimetre. The retroactive tenacity was found to be on the average 5·7 times greater than the absolute tenacity.

The tenacity of *glass* has been examined by Fairbairn and Tate (Proc. Roy. Soc. x. 6). The absolute tenacity determined by direct stretching was found to be for:

	Tenacity per sq. in. in lbs.
Flint glass (best; specific gravity 3·0782)	2413
Green glass (specific gravity 2·5284)	2896
Crown glass (extra white; specific gravity 2·4504)	2346

But from experiments on the resistance of glass globes to internal pressures, much higher values were found for the absolute tenacities, viz. for:

	Tenacity in lbs.
Flint glass	4200
Green glass	4800
Crown glass	6000

These results are regarded by the-authorsas more trustworthy than the former, because the globes were better annealed than the rods used in the first experiments.

Experiments on the resistance of glass to crushing were made upon small cylinders and cubes crushed between parallel steel surfaces by means of a lever. The cylinders were cut from rods drawn to the required diameter while hot, and then annealed. The cubes were cut from much larger portions, and were probably less thoroughly annealed. For this reason, the experiments on cylinders, which gave nearly twice the resistance afforded by the cubes, are regarded as the more trustworthy. The following table gives the mean results:

Resistance of Glass to Crushing.

	Mean crushing weight in lbs. per sq. inch.	
	For cylinders.	For cubes.
Flint glass	27582	13130
Green glass	31876	20206
Crown glass	31003	21762

COLCHICEINE, $C^{38}H^{47}N^{2}O^{11}$ (Oberlin, Ann. Ch. Phys. [3] l. 108).—An alkaloïd prepared from colchicine by acidulating the aqueous solution of that body with sulphuric or hydrochloric acid, concentrating the liquid to dryness over the water-bath, then adding water, and crystallising from alcohol the yellow mass which separates. At the same time there is produced, by the action of the acid on the colchicine (perhaps impure), a resin which dissolves in alcohol and in ether, and with deep red colour in ammonia or nitric acid. According to Oberlin, colchiceine exists ready formed in the seeds of *Colchicum autumnale.*

Colchiceine crystallises in colourless nacreous laminæ or needles, sparingly soluble in cold, more easily in boiling water, easily soluble in alcohol, wood-spirit, and chloroform. It melts at 155° C. and becomes coloured at 200°. It dissolves with deep-yellow colour in strong nitric acid; without colour in sulphuric, hydrochloric, and acetic acid. It is insoluble in alkalis, appears to unite with baryta, is coloured green by ferric chloride. The alcoholic solution is not precipitated by lead-salts, platinic or mercuric chloride, nitrate of silver, or tincture of galls.

Colchiceine exerts, sometimes at least, a poisonous action when injected into the stomach. Oberlin states (Compt. rend. liii. 1202), that 0·1 grm. killed rabbits in 12 hours, and 0·05 grm. in a few minutes; but according to another account (Ann. Ch. Phys. [3] l. 114), even 0·5 grm. produced only temporary symptoms.

COLCHICINE. This alkaloïd, which is contained in all parts of the *Colchicum autumnale*, and probably also in other species of *colchicum*, was discovered by Pelletier and Caventou (Ann. Ch. Phys. [2] xiv. 69), who however regarded it as identical with veratrine. It was further examined by Geiger and Hesse, who first, in 1833, (Ann. Ch. Pharm. vii. 274) recognised its separate identity, and has been more recently investigated by Hübschmann (Arch. Pharm. [3] xcii. 330), Aschoff, *ibid.* lxxxix. 4), Bley (*ibid.* 18), and others.

Preparation.—1. The bruised seeds of colchicum are macerated with alcohol containing sulphuric acid; the extract is treated with lime, the filtered liquid saturated with sulphuric acid, and the alcohol expelled by distillation. The concentrated aqueous solution is then decomposed with carbonate of potassium; the precipitate is dried, and dissolved in absolute alcohol; the solution is decolorised with animal charcoal; the filtered liquid is evaporated at a gentle heat; and the alkaloïd thus obtained, is purified by repetition of the treatment with alcohol and animal charcoal (Geiger and Hesse).—2. According to Hübschmann, a larger product is obtained by exhausting the seeds with 3½ pts. alcohol of 90 per cent., then distilling off the alcohol, precipitating the residual liquid with carbonate of potassium; exhausting the dried precipitate with ether, and finally with sulphuric acid, to separate resin; and re-precipitating with carbonate of potassium.—3. Aschoff boils the comminuted seeds with water, neutralises the decoction with lime-water; filters after boiling, and evaporates to the consistence of an extract; then exhausts the extract with alcohol, continuing the process as long as the alcohol acquires thereby a bitter taste. The residue left after the distillation of the alcohol, is dissolved in water and precipitated with tannic acid; the precipitate is washed and pressed, then dissolved in alcohol, and digested with a sufficient quantity of recently precipitated ferric hydrate at 30° C.; lastly, the filtrate is evaporated, and the residue treated with absolute alcohol, which dissolves out the pure colchicine.—4. Polex exhausts the bruised seeds with a mixture of 4 pts. ether and 1 pt. alcohol, evaporates to dryness, dissolves the residue in water, and purifies the dissolved alkaloïd with animal charcoal.

Bley and Aschoff, obtained from the seeds, as a maximum, 0·2 per cent. of colchicine.

Colchicine may likewise be prepared by similar processes from the flowers, leaves, and bulbs of the plant.

Properties.—Colchicine crystallises from its alcoholic solution, on addition of water, in colourless prisms and needles: the alcoholic or ethereal solution leaves it, on evaporation, in the form of a transparent varnish (Geiger). According to other chemists, colchicine is always obtained as an amorphous yellowish white powder. It has a persistently bitter taste, not burning like that of veratrine; it is inodorous, and does not, like veratrine, excite sneezing. According to Geiger, it has a very faint alkaline reaction, reddening rhubarbarin, and bluing reddened litmus paper. According to Bley, Aschoff, and Hübschmann, on the contrary, it is perfectly neutral. It is permanent in the air.

The composition of colchicine has not been satisfactorily determined. According to Bley, it contains 55·0 per cent. C, 7·4 H, and 13·0 N, which he represents by the empirical formula $C^{27}H^{20}N^{3}O^{11}$, although his results agree better with $C^{30}H^{23}N^{3}O^{10}$, or $C^{15}H^{23}N^{3}O^{5}$. Aschoff found 55·2 C, 6·2 H, and 2·8 N, whence he deduces the formula $C^{23}H^{21}NO^{11}$. The great difference in the nitrogen determinations, and certain differences in the properties of the base, as observed by these two chemists, seem to show that they must have been operating, either upon different bases, or on the same in very different degrees of purity.

Colchicine dissolves with moderate facility in water, according to Hübschmann, in less than 2 pts. at 22° C.; this property distinguishes colchicine from veratrine, which is insoluble in water. It dissolves easily in alcohol, less easily in pure ether; at 20° C., in 18 pts. ether of specific gravity 0·74. Chloroform dissolves it readily, and withdraws it for the most part from the aqueous solution on agitation.

Colchicine, when strongly heated, melts and decomposes with intumescence (according to Bley, it volatilises at 112° C.). Strong nitric acid colours it deep violet or blue, quickly changing to olive-green and yellow; strong sulphuric acid colours it yellowish-brown, not violet, thus affording a distinction from veratrine. Phosphoric acid and hydrochloric acid colour even dilute solutions of colchicine distinctly yellow; chromic acid colours the solution green. Chlorine-water renders the solution turbid, and on subsequently adding ammonia, it assumes a yellowish-red colour. Colchicine is precipitated of a kermes-brown colour from its aqueous solution by tincture of iodine; yellow by dichloride of platinum, white by tannic acid, the last-mentioned precipitate being soluble in alcohol, acetic acid, and alkaline carbonates.

The statements of different chemists regarding the behaviour of colchicine with bases and acids do not agree. According to Aschoff, colchicine is converted by caustic alkalis into a brown resinous mass, soluble in water and alcohol; it unites with baryta and lime, but does not decompose alkaline carbonates. According to Bley, a solution of colchicine mixed with carbonate of soda, yields by evaporation a non-crystalline mass, free from carbonic acid (?).

According to Geiger, colchicine neutralises acids completely, forming extremely bitter salts, with rough irritating after-taste; some of them, the sulphate for example, are crystallisable and permanent in the air. They are very soluble in water and in alcohol, the aqueous solutions yielding with iodine and with tincture of galls the same reactions as the pure base; caustic alkalis precipitate the colchicine from concentrated, but not from dilute solutions of the salts. Bley and Aschoff did not succeed in preparing crystallisable compounds of colchicine with acids. The salts were acid, and soluble in water and alcohol, excepting the tannate, which is insoluble in water.

Physiological action.—Colchicine is poisonous, even small doses causing violent vomiting and purging; $\frac{1}{12}$th of a grain killed a cat in twelve hours. Tannin is said to be a good antidote. In cases of poisoning by colchicine, the alkaloïd may be detected by treating the stomach and intestines with strong alcohol, evaporating the liquid, and again treating the residue with alcohol, or with alcohol and ether, and again evaporating. Colchicine then remains as an amorphous yellowish mass, which exhibits the above-mentioned reactions with mineral acids, tincture of iodine, and tannic acid.

COLCHICUM AUTUMNALE. The root and seeds of this plant are used in pharmacy; according to Coindot, however, the flowers are more active and to be recommended for the preparation of a tincture.

The flowers, according to Reithner, contain colchicine in combination with tannic acid, also sugar, pectin, gum, fat, wax, and resin. The dried flowers, without anthers, yield 4·05 per cent. ash (*a*); the dried anthers alone yield 4·15 per cent. ash (*b*), containing in 100 parts:

	a.	*b.*		*a.*	*b.*
Potash	37·4	40·0	Silicic acid (anhydrous)	7·7	0·8
Soda	8·5	6·1	Carbonic ,,	22·3	22·5
Lime	4·3	2·6	Sulphuric ,,	3·7	6·2
Magnesia	3·0	6·5	Phosphoric ,,	10·6	14·4
Alumina	0·3	trace	Chlorine	1·5	0·5
Ferric oxide	0·5	0·2			

The ripe seeds collected in July contain in 100 pts., according to Bley: 0·2 colchicine, 5 glucose, and 6 fixed oil, together with resin, extractive matter, cellulose, and traces of veratric acid and gallic acid.

The fresh bulbs contain, according to the same authority, 0·2 per cent. colchicine, 0·3 sugar, 0·5 colouring matter, 29·0 starch, together with gallic acid, extractive matter, cellulose, &c. Colman found also 21 per cent. starch. The starch may be extracted from the bulbs by washing with water; after prolonged washing, it is perfectly pure and tasteless. (Handw. d. Chem. ii. [3] 153).

COLCOTHAR VITRIOLI, also called *Crocus Martis.*—The brown-red oxide of iron which remains after the distillation of sulphuric acid from sulphate of iron; it is used as a polishing powder.

COLLETIIN. A crystallisable bitter principle, obtained from *Colletia spinosa* (order *Rhamnaceæ*). It forms needles insoluble in cold water and ether, sparingly soluble in boiling water, easily in alcohol. It is contained in the alcoholic tincture of the plant, which, according to v. Martius, is used in Brazil as a remedy for intermittent fever. (Handw.)

COLLIDINE. $C^8H^{11}N$.—An alkaloïd found, together with many others, among the products of the dry distillation of animal substances and of coal. It was discovered by Anderson in 1855 (Phil. Mag. J. [4] ix. 145, 214), who obtained it from bone-oil, and was afterwards found by Greville Williams in the bituminous shale of Dorsetshire (Chem. Soc. Qu. J. vii. 97), in coal tar, and in the impure quinoline obtained by the dry distillation of quinine and cinchonine (Chem. Gaz., 1855, p. 308). It is isomeric with ethyl-phenylamine, ethyl-picoline, dimethyl-phenylamine, and xylidine.

Preparation.—1. The portion boiling above 170° C. of the mixture of volatile bases obtained from bone-oil (i. 625), is mixed with a considerable quantity of strong nitric acid, which acts very violently upon it, thereby acquiring a deep red colour, and on boiling evolves nitrous acid fumes and an odour of bitter almonds. The part boiling at 182° C. must be well cooled while being mixed with the nitric acid, to prevent explosion. The acid solution, when mixed with water, becomes turbid, from the separation of a reddish-yellow oil, which seems to be impure nitro-benzene; the acid solution is filtered through moist paper, and the filtrate is boiled for some time to expel the last traces of the neutral oils, then saturated with potash and distilled. The oil which passes over with the water is repeatedly rectified, and the portion boiling between 178° and 180° is collected. The part of the mixture of bases boiling above 170° contains a considerable quantity of phenylamine, which cannot be removed, either by repeated rectification or by recrystallisation of the oxalate; by the action of nitric acid it is destroyed, whilst the alkalis homologous with collidine remain undecomposed.—The part boiling between 172°—180°, when treated in this manner, yields, by distillation with potash, an oil which begins to boil at 160°, and is composed for the most part of lutidine; while the portion boiling above 180° yields an oil, the greater part of which goes over at 179°, and when rectified yields pure collidine. (Anderson.)—2. When the mixture of chinoline with other bases, which is obtained by the distillation of cinchonine with potash, is subjected to oft-repeated fractional distillation, the portion boiling between 177° and 182° C. yields, with solution of platinum, chloroplatinate of collidine. This salt may also be obtained from the fraction boiling between 182° and 187°, if another base mixed with it has previously been destroyed by means of nitric acid. (Gr. Williams.)

3. Gr. Williams mixes the naphtha obtained by the distillation of the bituminous shale of Dorsetshire with sulphuric acid; boils with water until all the tar is converted into resin, and all the pyrrol is removed; concentrates the liquid; neutralises with lime or potash, and distils; supersaturates the distillate with hydrochloric acid; removes the non-basic oil; then supersaturates the acid liquid with lime or potash, and distils. The distillate is freed from ammonia by washing with strong potash, dried by solid hydrate of potash, and fractionally distilled until liquids of constant boiling points are obtained. The small portion which passes over between 132° and 138° C. is lutidine mixed with a little picoline (from the mother-liquor of the chloroplatinate of lutidine, the double salt of picoline is obtained); the portion obtained between 149° and 155°, and between 177° and 182° is pure lutidine; and that which passes over between 227° and 258° is collidine.—4. The mixture of volatile bases obtained in like manner from coal-tar oil is treated, as in Anderson's process, with nitric acid, and subjected to repeated fractional distillation. The portion which distils between 150° and 155° C. is lutidine, and afterwards a small quantity of collidine passes over. (Gr. Williams.)

Properties.—Collidine is a colourless, oily liquid, having a strongly aromatic, not unpleasant odour. Specific gravity, 0·921; boiling point, 179° C. It forms white fumes when a glass rod moistened with hydrochloric acid is held over it. It is insoluble in *water*, but takes up a small quantity of that liquid, which it gives up again to hydrate of potassium. It dissolves readily in *alcohol*, *ether*, and *oils*, both fixed and volatile.

Collidine dissolves readily in *acids*, but does not neutralise them. It does not precipitate the salts of barium, calcium, magnesium, manganese, or nickel, but throws down alumina, chromic oxide, oxide of zinc, ferric oxide, and mercurous oxide from their solutions: it also precipitates nitrate of lead, but not the neutral acetate. (Anderson.)

Chloromercurate of Collidine is obtained as a white, curdy, flaky precipitate, and crystallises from hot water in needles. The *chloroplatinate*, $C^8H^{11}N.HCl.PtCl^2$, forms orange-yellow flakes. (Anderson.)

Ethyl-collidine, $C^{10}H^{15}N = C^8H^{10}(C^2H^5)N$.—The hydriodate of this base is obtained as an oily liquid by heating collidine to 100° C. with iodide of ethyl. On decomposing it with nitrate of silver, removing the excess of silver by hydrochloric acid, and mixing the filtered liquid with dichloride of platinum, the *chloroplatinate*, $C^{10}H^{15}N.HCl.PtCl^2$ is obtained, as a finely-divided, crystalline, sparingly soluble precipitate (Anderson, Phil. Mag. [4] ix. 221).

COLLINIC ACID. $C^6H^4O^2 = \left.\begin{matrix}C^6H^3O\\H\end{matrix}\right\}O$. (Fröhde [1860], J. pr. Chem. lxxx. 344).—An acid belong to the aromatic series $C^nH^{2n-8}O^2$, found among the products of the oxidation of the albuminoïdal substances, and of gelatin. To obtain it, the mixture of acids produced by oxidising gelatin with chromic acid is saturated with carbonate of sodium, and evaporated to drive off the neutral volatile bodies; the nearly dry salts are decomposed by sulphuric acid; and the solid acid thereby separated is filtered and washed. If the residue be then treated with a small quantity of boiling water, the greater part of the collinic acid remains in fused reddish masses (about 0·96 grm. collinic acid from 1 kilogrm. gelatin), while the other acids, especially the benzoic acid, dissolve completely, together with a small portion of the collinic acid. By recrystallisation from water, it may be obtained in small crystals having a prismatic aspect.

Collinic acid has a sour, pungent taste; dissolves sparingly in boiling water, easily in ether. When heated with water, it melts at 97° C, and then solidifies at 93° or 94°; in the dry state, it does not melt till heated somewhat above 100°. On cooling, is solidifies to a waxy mass generally having a radiate texture. At a higher temperature, it sublimes. When set on fire, it burns with a bright but smoky flame. Boiled with carbonate of sodium, it yields humoïd flakes. Heated with hydrate of potassium, it decomposes, but does not appear to yield any volatile acids.

Collinic acid is a strong acid, dissolving in caustic alkalis, and decomposing carbonates. It forms both neutral and basic salts. The silver-salts decompose with facility.

A solution of *collinate of ammonium* gives off ammonia and becomes acid on boiling; acid vapours, however, escape at the same time. The *barium-salt*, $2C^6H^3BaO^2$ + aq., is crystalline, easily soluble in water, gives off water of crystallisation when heated, melts and blackens at a higher temperature. The *ferric salt* is a light, yellowish-red precipitate, which dissolves with blood-red colour on addition of a small quantity of acid. The *neutral silver-salt*, $C^6H^3AgO^2$, is obtained in crystalline scales by precipitating the ammonium-salt with nitrate of silver, dissolving the precipitate in water, and evaporating over oil of vitriol. The mother-liquor when evaporated gives off acid and yields grey granules of a basic salt, $Ag^2O.2C^6H^3AgO^2$; by continued heating of the solution, the silver-salt is reduced.

An acid isomeric, if not identical with collinic acid, is produced by oxidising coal-tar naphtha with dilute nitric acid (De La Rue and Müller, Chem. Soc. Qu. J. xiv. 54), or sulpho-benzolic acid with chromic acid. (Church, *ibid.* 53.)

COLLINIC ALDEHYDE. *Hydride of collyl.*—This compound occurs, according to Fröhde (J. pr. Chem. lxxx. 325), among the neutral volatile products of the oxidation of the albumoïds, and of gelatin; it appears to have been previously noticed by Schlieper and Guckelberger. It is probably C^6H^6O (isomeric with phenic acid). It has not yet, however, been obtained pure, especially not free from hydride of benzoyl. It is a colourless viscid oil, smelling somewhat like oil of cinnamon, and turning yellow from oxidation when exposed to the air. By prolonged boiling with potash-ley, it is converted into collinic acid. By continued contact with ammonia, it is converted into a white crystalline substance, probably the homologue of hydrobenzamide.

According to Schlieper (Ann. Ch. Pharm. lix. 22), this oil having the odour of cinnamon is converted by the action of dry chlorine, with elimination of hydrochloric acid, into a white substance which is insoluble in ether, and when heated with potash-ley forms a blood-red volatile oil; the potassium-salt, on addition of an acid, emits the odour of phenic acid.

COLLODION (from κολλώδης, glutinous). A solution of pyroxylin (gun-cotton) in ether. The solubility of this substance in ether, varies considerably according to the mode of its preparation; the most explosive kinds are by no means the most soluble (see PYROXYLIN). The best mode of obtaining pyroxylin, for the preparation of collodion, is to mix 16 pts. of nitrate of potassium with 12 pts. of common and 12 pts. of fuming oil of vitriol; immerse in this mixture, as soon as it is made, 1 pt. of cotton wool, stir it about for five minutes, and then wash it well with water.

To prepare collodion, pyroxylin obtained in the manner just described is shaken up with 16 pts. ether, in a bottle which can be closed. 1 or 2 pts. of absolute alcohol are added after a while, and the vessel shaken at intervals, till the solution is complete. Lassaigne pours 26 pts. of ether on 1 pt. of pyroxylin, and mixes the resulting jelly with 18 pts. more of ether. According to other methods, 1 pt. of pyroxylin is treated with from 20 to 120 pts. of ether, and from 4 to 16 pts. of alcohol. The solution obtained by either of these methods is left to stand till the undissolved parts have settled down.

Pyroxylin is said also to be rendered perfectly soluble in ether by moistening it with acetone.

Collodion is a clear colourless gummy liquid, insoluble in water and alcohol, but soluble in ether; when exposed to the air, it soon dries up, leaving a transparent or translucent residue, which becomes strongly electric by friction, explodes less easily by heat, pressure, or percussion than flocculent pyroxylin, and is soluble in ether containing alcohol and in strong acetic acid.

When the ethereal solution is suffered to evaporate in a thin film, it dries up quickly to a thin transparent membrane, which possesses great adhesiveness, is tolerably impervious to air, and is not dissolved either by water or by alcohol. These properties render collodion very useful for a variety of purposes. It is employed with great advantage in surgery to form an air-tight covering for wounds and burns; when spread over an incised wound, it greatly promotes the healing by drawing the edges of the wound together, the film of collodion contracting strongly as the ether evaporates. As the collodion film is rather solid, and has but little elasticity, it has been recommended to melt 2 grms. of Venice turpentine with 2 grms. castor oil and 2 grms. of white wax, mix the fused mass with 6 grms. of ether, and add the whole to 140 grms. of collodion.

Collodion is also used as an envelope for caustic substances, in order to confine their action exactly to the desired spot. Pills may be coated with it, so as to render them tasteless, and wood, paper, and other fabrics may be rendered water-proof by being covered with it.

Collodion is also largely used in photography. A thin layer of the solution, mixed with iodide, bromide, or chloride of potassium, or ammonium, is spread uniformly over a glass plate, then treated with a solution of nitrate of silver to form the sensitive film. It appears to be essential to use anhydrous ether and alcohol for the solvent, in order to insure uniform evaporation.

Another application of collodion is for making balloons. For this purpose, a solution of collodion, not too thick, is poured into a flask of suitable dimensions, which is turned about to spread the liquid uniformly over it, and then inverted to allow the excess to run out. The ether is now evaporated from the film of liquid which adheres to the glass, by blowing into the flask with a pair of bellows, whereby the collodion is left in the form of a thin membrane on the surface of the glass. To remove it, the edges of the film are loosened from the glass, a glass tube of suitable character is inserted into the neck of the flask, so that the balloon may adhere to it, and the air is slowly drawn out with the mouth; the balloon then detaches itself from the vessel, contracts, and is easily withdrawn through the neck. It must be immediately blown out and tied at the neck, so that it may dry in the distended state. Small and thin balloons do not diminish much in volume as they dry; but larger ones contract strongly: this contraction may, however, be prevented by drying the balloon in warm air. Collodion balloons may be made much lighter than those of gold-beater's skin, so that much smaller ones will rise in the air when filled with detonating gas (2 vol. H and 1 vol. O). They may be made so thin that a balloon containing 100 cubic centimetres shall weigh only 0·03 grms. when empty, and 0·04 when filled with hydrogen; now the weight of an equal volume of air is 0·13 grms., consequently such a balloon will rise rapidly in the air. Hydrogen diffuses quickly through their pores. Collodion balloons become strongly electric by slight friction; when very thin, they exhibit beautiful interference-colours. (Handw. d. Chem. ii. [2] 158).

COLLYL, HYDRIDE OF. See Collinic Aldehyde.

COLLYRITE. A hydrated silicate of aluminium, $2Al^4O^6.SiO^2 + 10aq.$, found at Esquerra in the Pyrenees, near Schemnitz in Hungary, and near Wessenfels in Saxony. It is white, very soft, earthy, unctuous to the touch, adheres strongly to the tongue. In water it becomes transparent and crumbles to pieces: it dissolves in acids and the solution yields a jelly by evaporation (Gm. iii. 411.)

COLOCYNTHIN. A bitter substance contained in the pith or pulp of the fruit of *Cucumis colocynthis* (bitter apple), a plant growing wild in the Grecian Archipelago, also in Egypt, and other parts of North-eastern Africa. It has been examined by Vauquelin (J. Phys. lxxxiv. 338), Braconnot (J. Pharm. x. 416), Herberger

(*Buchner's Repert.* xxxv. 368), **Bastick** (Pharm. J. Trans. x. 289), and lastly by **Walz** (Arch. Pharm. xcvi. 241; xcix. 338), who regards it as a glucoside = $C^{56}H^{84}O^{23}$.

It is prepared from the pulp of the fruit separated from the seeds. Vauquelin exhausted the pulp with cold water, and evaporated the extract, the colocynthin then separating in oily drops, which solidified on cooling. **Lebourdais** (Ann. Ch. Phys. [3] xxiv. 58) precipitates the aqueous extract with neutral acetate of lead, and treats the filtered liquid with animal charcoal, which takes up both the colouring matter and the bitter principle. The charcoal is then washed with water. As long as the liquid which runs through it acquires a bitter taste, nothing but pure colocynthin is dissolved; and on again precipitating it with animal charcoal, boiling the charcoal with alcohol, and leaving the solution to evaporate, the colocynthin separates in small warty groups. Walz exhausts the fruit with alcohol of 0·840; evaporates; dissolves the extract in water; precipitates the filtrate with neutral and with basic acetate of lead; removes the lead from the filtered liquid by sulphuretted hydrogen; and precipitates the colocynthin by tannic acid. The precipitate, which becomes resinous on heating the liquid, is dissolved in alcohol; the tannic acid is precipitated with basic acetate of lead; the filtrate, freed from lead, is heated with animal charcoal; the liquid is again filtered and evaporated; and the dry residue exhausted with ether, which leaves the colocynthin undissolved.

Colocynthin is intensely bitter, and acts as a drastic purgative. It is soluble in water, alcohol, and ether. The aqueous solution is precipitated by chlorine; it also yields, with acids and with deliquescent salts, a viscous precipitate insoluble in water. The solution is also precipitated by acetate of lead and many other metallic salts.

Colocynthin boiled with acids is resolved, according to Walz, into sugar (7·7 per cent.) and **colocynthein**, $C^{44}H^{64}O^{13}$, which remains as a resinous mass, and may be purified by washing with water, solution in absolute ether, and evaporation.

COLOCYNTHITIN. A body contained, according to **Walz** (N. Jahrb. Pharm. ix. 225), in the alcoholic extract of bitter apple (see CUCUMIS). When this extract is treated with water, colocynthitin remains undissolved; and on treating this residue with ether, digesting the solution with animal charcoal, evaporating the filtrate, exhausting with hot absolute alcohol, and leaving the filtered liquid to cool, colocynthitin separates in white microscopic crystals. It is soluble in ether.

COLOMBIC ACID. An acid obtained by **Bödecker** (Ann. Ch. Pharm. lxix. 47), from colombo-root, the root of *Menispermum palmatum*, L., *Cocculus palmatis*, Dec. To prepare it, the alcoholic extract of the root is exhausted with water or lime-water, and the solution treated with hydrochloric acid. Colombic acid is then precipitated in white amorphous flakes, which are strongly acid, nearly insoluble in cold water, very soluble in alcohol, sparingly soluble in cold ether. By the evaporation of its alcoholic solution, it is obtained in the form of a yellow varnish.

The alcoholic solution of colombic acid is not precipitated by acetate of copper, but yields with neutral acetate of lead a copious white precipitate, which, when dried at 130° C. contains 30·53 per cent. lead oxide, agreeing nearly with the formula $3Pb^2O.2C^{42}H^{44}O^{12}$. Dried at 100° C., it contains in addition $5H^2O$.

The acid itself, dried at 115° C., gave by analysis 66·64 per cent. C, and 6·29 H, agreeing nearly with the formula $C^{42}H^{46}O^{13}$, or $C^{42}H^{44}O^{12}.H^2O$.

COLOMBIN. *Colombo Bitter.* $C^{21}H^{22}O^{7}$. (**Wittstock** [1830], Pogg. Ann. xix. 298.—**Liebig**, *ibid.* xxi. 30.—**Bödecker**, Ann. Ch. Pharm. lxix. 39.)—A neutral substance which constitutes the active principle of colombo root. Bödecker prepares it by exhausting the root with alcohol of 75 per cent., drying the extract as completely as possible, dissolving it in water, agitating the solution several times with an equal volume of ether, decanting the ethereal liquid with a siphon, filtering, and evaporating off the greater part of the ether. The colombin then crystallises out, and is purified by rinsing it with cold ether, pressing it between bibulous paper, dissolving it in boiling absolute ether, and concentrating the solution to one-fourth of its bulk. The greater part of the colombin then separates out quite white, the rest remaining dissolved in the ether, together with the fat contained in the root. To free the colombin entirely from fat, it must be repeatedly crystallised from ether; when quite pure it will dissolve in acetic acid without separation of oil-drops.

Colombin crystallises in colourless prisms belonging to the trimetric system. Observed combination, $\infty P . \infty \bar{P} \infty . \infty \breve{P} \infty . \bar{P} \infty$. Inclinations of the faces, $\infty P : \infty P = 125° 30'$; $\infty P : \infty \bar{P} \infty = 152° 45'$; $\infty P : \infty \breve{P} \infty = 117° 15'$; $\bar{P} \infty : \bar{P} \infty = 176° 19'$; $P \infty : \infty \breve{P} \infty = 123° 39·5'$; $\infty P : \bar{P} \infty = 119° 31'$. The faces are brilliant, but the crystals do not cleave in any direction (**G. Rose**, Pogg. Ann. xix. 441). Colombin is inodorous, very bitter, and perfectly neutral to vegetable colours. It melts at a gentle heat. It dissolves but sparingly in cold water, alcohol, and ether, but imparts to them a strong bitter taste. Boiling alcohol of specific gravity 0·835 dissolves from $\frac{1}{40}$

to $\frac{1}{80}$ of its weight of colombin. It dissolves to a small amount in volatile oils, and more freely in potash, whence it is precipitated by acids in its original state. Acetic acid dissolves it and deposits it in the crystalline state on evaporation. Strong sulphuric acid dissolves it with orange colour, gradually changing to deep red, and on adding water to the solution, brown flakes are deposited. Solutions of colombin are not precipitated by any metallic salts or by tincture of galls.

Colombin yields, according to the mean of Bödecker's analyses, 65·20 per cent. C and 5·98 H, the above formula requiring 65·3 C, 5·7 H, and 29·0 O. It does not form any definite compound, so that its atomic weight cannot be determined.

COLOMBO ROOT. The root of *Cocculus palmatus*, Dec., contains colombin, berberine, colombic acid (probably as colombate of berberine), besides starch, colouring matter, &c. The colombic acid and berberine may perhaps be formed from colombin by addition of the elements of ammonia (Bödecker):

$$\underset{\text{Colombin.}}{4C^{21}H^{22}O^7} + 2NH^3 = \underset{\text{Berberine.}}{2C^{21}H^{19}NO^4} + \underset{\substack{\text{Colombic}\\\text{acid.}}}{C^{42}H^{44}O^{15}} + 5H^2O.$$

The root acts with violence on the animal organism; a grain of the dry extract prepared with ether and freed by water from fat and wax, killed a rabbit when introduced into a wound. This active property appears to be due to the colombin. (Buchner.)

COLOPHANE. A constituent of icica resin (*q. v.*), containing, according to Scribe (Compt. rend. xix. 129), $C^{20}H^{30}O^2$. It is yellow, amorphous, easily soluble in alcohol, melts above 100° C., is insoluble in aqueous alkalis, and reacts neutral.

COLOPHENE. $C^{20}H^{32}$ or $C^{40}H^{32}$. (H. Deville, Ann. Ch. Phys. [2] lxxv. 66; [3] xxvii. 85.)—A hydrocarbon polymeric with oil of turpentine, obtained by distilling that oil with strong sulphuric acid, or by distilling hydrate of turpentine-oil with phosphoric anhydride. In either case, terebene ($C^{10}H^{16}$) passes over first; afterwards, when the heat rises above 210° C. colophene distils; it is purified from sulphur and a substance resembling colophony by repeated rectification, at last over antimonide of potassium. It may also be obtained by the rapid distillation of colophony, the product being purified in like manner.

Colophene is an aromatic oil, colourless by transmitted light, and exhibiting by reflected light a dark indigo-blue iridescence. Specific gravity, 0·940 at 9° C., 0·9394 at 25°. Boiling point between 310° and 315°. Vapour-density = 11·13 (probably only twice as great as that of oil of turpentine, therefore = 9·526). Refracting power = 1·517 (Becquerel and Cahours), 1·5212 (Deville). It has no action on polarised light.

Colophene absorbs *chlorine gas* without evolution of hydrochloric acid, becoming hot, and changing to a resin like colophony, which separates in yellow spherules from its solution in absolute alcohol. If, when the absorption of chlorine has ceased, the product be heated to fusion in the stream of chlorine, a large quantity of hydrochloric acid is evolved, and Deville's *chlorocolophene* = $C^{20}H^{24}Cl^8$ is formed, which however still contains a resin removable by alcohol, and when distilled, gives off hydrochloric acid, yields a distillate of colophene and hydrochlorate of colophene, and leaves charcoal.

Hydrochlorate of Colophene.—Colophene absorbs hydrochloric acid gas, with rise of temperature, and acquires an indigo-colour. The hydrochlorate gives up nearly all its hydrochloric acid when treated with chalk, and when distilled with baryta, yields Deville's *colophilene* = $C^{20}H^{32}$, which does not exhibit the dichroism of colophene, and has a refracting power for light = 1·5175. (Deville, Becquerel, and Cahours, Pogg. Ann. li. 427–433.)

Colophene from Camphor. (Claus, J. pr. Chem. xxv. 266.—When camphor is distilled with an equal weight of iodine, hydriodic acid is evolved, camphin passes over at 180° C., and charcoal, iodine, campho-creosote and colophene remain behind (i. 728). On increasing the heat, the two latter substances distil over as a bluish-green oil, which is deprived of its creosote odour by agitation with potash, but cannot be obtained quite pure, even by distillation over lime and finally over potassium.

It is a thick, yellowish oil, with violet iridescence, having a high boiling point, a mild taste, and an odour of violets, and burning with a bright fuliginous flame. It is perhaps identical with colophene from oil of turpentine or from colophony.

It is not soluble in *water* or in weak *alcohol*, but dissolves in *ether*, *oil of turpentine*, *rock-oil*, and *camphine*. When 2 drops of it are dissolved in 2 drachms of alcohol, the solution, after agitation with animal charcoal, exhibits a fine dark blue colour by reflected light.

COLOPHILENE. The hydrocarbon $C^{20}H^{32}$ obtained from Deville's hydrochlorate of colophene (*vid. sup.*)

COLOPHOLIC ACID of Unverdorben; *γ-resin of Colophony* of Berzelius. The constituent of colophony which is least soluble in alcohol, and is produced by the action of heat on pinic acid. It is therefore present in colophony in variable quantity, according as that substance has been more or less heated during fusion; the darker varieties contain about one-tenth. Colopholic acid is said to be likewise produced when pinic acid is distilled till a third of it has passed over.

Colopholic acid is brown, sparingly soluble in alcohol of 67 per cent., more readily in presence of pinic acid. It has a stronger affinity for bases than pinic acid; nevertheless the colopholates exactly resemble the pinates.

COLOPHONIC ACIDS. The resinous acids, pinic, pimaric, sylvic and colopholic, which are present in colophony.

COLOPHONITE. A variety of garnet, so called from its brown colour, resinous lustre, and easy fusibility. (See GARNET.)

COLOPHONONE. $C^{11}H^{18}O$. (Schiel, Ann. Ch. Pharm. cxv. 96).—An oil occurring among the more volatile products of the dry distillation of colophony; it is separated by fractional distillation. It is colourless, mobile, highly refractive, of specific gravity 0·84, boils at 97° C.; vapour-density about 5·1. When heated above its boiling point in a close vessel, it turns brown, and emits an odour of peppermint. It mixes with sulphuric acid, and on addition of water, a green oil separates, having an odour of thyme and rosemary. Hydrochloric acid acts in like manner; nitric acid converts it into a resin. With potassium, it gives off gas, and is converted into a brown mass, subsequently turning yellow.

COLOPHONY. *Rosin, Colophonium, Colophane, Arcanson, Brai sec, Geigenharz.*—The resinous substance which remains when turpentine or pine-resin is heated till the water and volatile oil are expelled. It is for the most part a mixture of several resinous acids, viz., pinic acid (the α-resin of Berzelius), which forms the principal part, sylvic acid (β-resin), and colopholic acid (γ-resin), sometimes also pimaric acid. These acids, which are mixed in various proportions, are all isomeric, their common formula being $C^{20}H^{30}O^2$ or $C^{40}H^{30}O^4$. They are perhaps formed by oxidation of turpentine oil:

$$2C^{10}H^{16} + O^3 = C^{20}H^{30}O^2 + H^2O.$$

Colophony is either pale yellow and transparent (*C. album*) or brownish-yellow and translucent (*C. commune*), according to the degree of heat to which it has been exposed. By distillation with steam under a pressure of about ten atmospheres, it may be obtained very nearly colourless (*Hunt and Pochin's Patent*, 1858, No. 925). It has a vitreous lustre, is brittle in the cold, has a conchoïdal fracture, and yields a yellowish powder. Its specific gravity varies from 1·07 to 1·08. It is insoluble in water, but dissolves easily in alcohol, ether, wood-spirit, and oils both fixed and volatile. Rock-oil dissolves only a portion of it; the undissolved part is said to be identical with pinic acid altered by the action of the air. Nitric acid dissolves and decomposes it at the same time.

Colophony, being a mixture of acids, unites with bases. The compounds which it forms with the alkalis are soaps soluble in water. It is easily saponified either by caustic alkalis or by their carbonates.

Colophony softens at 69° or 70° C. and melts at 135°. At a higher temperature it gives off volatile oils, acquiring a darker colour, and yields colopholic acid. When quickly heated in a retort, it distils partly undecomposed, partly resolved into gases, volatile oils, viz. Deville's terebene and colophene, and perhaps other hydrocarbons, finally yielding viscid oils, with a small residue of carbonaceous matter. When the distillation is performed on the large scale in cast iron retorts, the gases evolved in the first half of the distillation contain, besides the constituents of the air, 15 per cent. carbonic anhydride, 11·5 carbonic oxide, 5·9 ethylene and tetrylene; at a higher temperature, the oxygen disappears, the proportion of carbonic anhydride increases, and lastly a small quantity of marsh-gas is formed. The first portion of the liquid distillate is a yellow, mobile, strong-smelling liquid, known in commerce as *essence of rosin* (*vive essence, Harzessenz*); it yields by fractional distillation, first colophonone (*q. v.*), and afterwards an optically indifferent camphene (i. 724), boiling at 160° C., having the odour and other properties of oil of turpentine, and perhaps identical with Deville's terebene. At a later stage of the dry distillation, a viscid fluorescent oil passes over, called *rosin-oil* or *paraffine-oil*, which, after being treated with quick-lime, corresponds in composition to the formula $C^{30}H^{40}O$. After rectification, it no longer exhibits fluorescence, and if again treated with lime, gives the formula $C^{30}H^{28}O$ (Schiel, Ann. Ch. Pharm. cxv. 96). At a red heat, colophony yields a mixture of gases burning with a very bright flame, which it has been attempted, though without much success, to use as an illuminating gas.

Colophony is extensively used in making varnishes and cements, in the caulking of ships, in the preparation of plasters and ointments, and as a reducing agent in the soldering of metals. Large quantities are consumed in the manufacture of yellow soap. A well known use of it is for covering the bows of violins, to prevent the bow from slipping over the strings without producing vibration. Of the products obtained by the dry distillation of colophony, the more volatile oil is used in place of turpentine-oil, the more viscid rosin-oil for soap-making, and for lubricating cartwheels, &c. (Handw. d. Chem. i. [3] 160.)

COLORIMETER. An instrument for measuring the depth of colour in a liquid by comparison with a standard liquid of the same tint. The comparison is made either by varying the depth of the stratum of liquid under examination till it exhibits the same intensity of colour as the normal liquid, and then measuring the depth of the stratum, — or by diluting the stronger-coloured liquid with water, till equal columns of the two exhibit the same depth of colour.

COLORIN. A colouring matter obtained by Robiquet and Colin from madder, since shown to be impure alizarin.

COLOSTRUM. The milk of mammalia secreted in the first few days after parturition, before the access of milk-fever. It is distinguished from ordinary milk by containing a larger amount of solid constituents, also a larger proportion of fat, casein, and milk-sugar. (See MILK.)

COLOUR. (See LIGHT).—A table of oil painters' colours, with notices of their chemical and artistical qualities, drawn up by W. Linton, is given in *Ure's Dictionary of Arts, Manufactures, and Mines*, vol. i. p. 803; see also *Chimie des Couleurs pour la Peinture à l'Eau et à l'Huile*, par. J. Lefort. 12mo. Paris, 1855.

COLOURING MATTERS. This term is usually restricted to coloured compounds of vegetable or animal origin, sometimes more especially to such as exist ready formed in the bodies of plants and animals, or are easily formed from them by natural processes, such as oxidation or fermentation. Accordingly, it would be applied to such bodies as indigo, Indian yellow, and carmine, rather than to compounds like aniline-purple or murexide, which are formed by complicated artificial processes. This restriction of the term must not, however, be regarded as absolute, since many artificial organic coloured compounds resemble the natural colouring matters in their most essential properties, especially in those which render them available as dyes.

Colouring matters occur in all the organs of plants and animals. Many are obtained from roots, as alkanet, turmeric, madder, &c.; from the stems, as from sandal-wood, log-wood, Brazil-wood, &c.: leaves, flowers, fruits, and seeds are also rich in colouring matters. Of some insects, as the cochineal-insect, the entire substance is used as a dye; certain liquids of the animal organism, as the blood and bile, are also strongly coloured. Colouring matters rarely exist either in plants or animals in the separate state; indeed their separation is often a matter of considerable difficulty. Many do not exist ready formed in plants, but are produced from originally colourless compounds by oxidation or fermentation; in some instances, also, by the action of oxygen in presence of alkalis.

Colouring matters are for the most part either red, yellow, or blue, the last being the least numerous. Only one green colouring matter occurs in nature, namely, the chlorophyll of leaves.

Colouring matters have generally a saccharine and somewhat harsh taste; they are inodorous, some of them, as indigotin and alizarin, crystallise readily; others are of a resinous character. Many are volatile, as alizarin; but they must always be distilled with caution, as a heat of 150° C. is often sufficient to decompose them.

All colouring matters are affected by light, mostly absorbing oxygen under its influence, and becoming more or less decolorised. The green colour of chlorophyll on the contrary requires the presence of light for its development.

Many colouring matters are soluble in water, others only in alcohol, ether, or volatile oils; in some cases, the presence of an acid facilitates the solution, although the colouring matter may not actually possess basic properties, *e.g.* hæmatosin, indigotin, alizarin, purpurin; others on the contrary, as carthamin and santalin, dissolve readily in alkalis.

The tint of colouring matters is modified in various degrees, and sometimes completely destroyed, by chemical reagents. The alkalis turn the naturally red colour of litmus to blue, many vegetable blue colours to green, and the yellow of rhubarb or turmeric to brown. The alkaline compounds of alizarin are of a rich violet colour, though alizarin itself is reddish yellow. All colouring matters are decomposed by concentrated alkalis.

Many metallic oxides, *e.g.* alumina and oxide of tin, form chemical compounds with colouring matters. Such compounds are called lakes. Many salts also, especially those of aluminium, iron, and tin, act upon colouring matters so as to form compounds by means of which the colouring matter is fixed upon organic tissues; such substances are called mordants.

Porous substances, especially animal charcoal, absorb colouring matters without decomposing them; thus, if an infusion of logwood be decolorised by filtration through animal charcoal, the colouring matter may be recovered by treating the charcoal with a weak alkaline ley.

All organic colouring matters are destroyed by chlorine in presence of water, the action consisting, in most cases, of a direct oxidation of the colouring matter, by oxygen set free by the decomposition of water. Sometimes, however, the chlorine takes hydrogen from the colouring matter itself and partly replaces it.

Oxygen in the nascent state likewise acts as a decolorising agent, when derived from other sources; thus, peroxide of hydrogen quickly destroys the colour of organic bodies, and indigo is bleached by nitrous acid.

Sulphurous acid decomposes and bleaches many colouring matters, sometimes by abstracting oxygen, sometimes by uniting with the colouring matter and forming a colourless compound. It is a valuable bleaching agent in many cases, especially for silk and wool, because it destroys the colouring matter without acting on the tissue, whereas chlorine would act very injuriously upon it. Fruit stains are easily removed from linen by washing with a weak solution of sulphurous acid, or by holding the moistened cloth over burning sulphur; care must be taken, however, to wash it well afterwards, or the sulphuric acid produced in the reaction will destroy the fibre.

Many reducing agents, such as nascent hydrogen, sulphydric acid, alkaline sulphides, ferrous salts, &c., decolorise colouring matters in such a manner that the colour is restored by mere exposure to the air; thus, blue indigo is converted into white indigo by the action of these bodies, but recovers its blue colour by atmospheric oxidation. The action consists either in a direct deoxidation of the colouring matter, or in a combination of the colouring matter with hydrogen derived from the decomposition of water. Thus white indigo, C^8H^6NO, is formed from blue indigo, C^8H^5NO, by addition of 1 at. hydrogen. (*Traité de Chimie générale, par Pelouze et Frémy*, 2^{me} ed. v. 492; *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 806.)

COLUMBITE. See NIOBITE.

COLUMBIUM or **NIOBIUM.** A metal originally discovered in columbite from Massachusetts, and since shown to exist in the tantalite (or rather columbite) of Bodenmais in Bavaria, also in Samarskite, pyrochlore, wöhlerite, euxenite, and a variety of pitchblende from Satersdalen in Norway. It was discovered by Hatchett in 1801. Wollaston erroneously supposed it to be identical with tantalum, the metal discovered a short time afterwards by Ekeberg in Finland tantalite. This opinion was long received as correct, and columbium is even now spoken of in most Manuals of Chemistry as identical with tantalum; but the researches of H. Rose have shown that this supposed identity does not exist. In short, columbium is identical, not with tantalum, but with Rose's niobium (*q. v.*)

COMBUSTION. This term properly denotes the development of light and heat accompanying chemical combination. It is sometimes used as synonymous with *inflammation*, which, however, is better restricted to those cases of combustion in which the products are gaseous, in other words, in which flame is produced. *Ignition* is the incandescence of a body produced by extrinsic means, without change of its chemical constitution.

The earlier chemists, feeling daily the necessity of fire to human existence, and astonished at the changes which this power seemed to produce in charcoal, sulphur, the metals, and other bodies, regarded combustion as the grand and essential phenomenon of chemistry. At the beginning of the eighteenth century, Stahl, of Prussia, by applying the views of Albertus Magnus and Becher respecting combustion to the whole collection of facts discovered by himself and others, and uniting them into a connected whole, laid the foundation of the first system of chemistry. This system received the name of the "Phlogistic Theory," because Stahl assumed that all combustible bodies contain one and the same principle of combustion called *Phlogiston*, the escape of this substance from a heated combustible body being supposed to produce the phenomenon of combustion or fire, and its addition to a burnt body to restore the combustibility of that body: thus, phosphorus was regarded as a compound of phlogiston and phosphoric acid; lead of phlogiston and lead-earth or calx of lead, the substance now called oxide of lead. When a calx or earth was reduced to the metallic state by heating it with charcoal (a body rich in phlogiston), it was supposed that the burnt body took phlogiston from the charcoal, and was thus restored to the combustible state.

An obvious defect of the phlogistic theory was that it took no account of the essential part which the air plays in all ordinary cases of combustion, a fact suggested by common experience, and fully demonstrated by the discoveries of Scheele, Cavendish, and Priestley. Moreover it had long been known that many combustible bodies, the metals for example, do not lose, but gain weight when burnt; and towards the end of the eighteenth century Lavoisier showed, by experiments on combustion, made with a degree of accuracy in the determination of weights and volumes, quite unknown before his time, that whenever a body burns in the air or in oxygen gas, the oxygen enters into combination with the burning body, and the weight of the product is exactly equal to the sum of the weights of the combustible body burnt and of the oxygen consumed. It was also shown that, in the reduction of a metal from its calx (or oxide) by charcoal, the latter body takes oxygen from the calx and leaves the metal in the free state. In short, wherever the phlogistic theory supposed that phlogiston was removed from a body, Lavoisier's experiments showed that oxygen was taken up, and wherever, according to the former theory, phlogiston was supposed to be added, Lavoisier showed that oxygen was removed. This system of chemistry, called the "Antiphlogistic Theory," did not, however, meet with immediate acceptation from the majority of chemists, the advocates of the phlogistic system maintaining that the increase of weight of metals and other bodies in burning might be explained by abscribing to phlogiston a principle of levity,—in other words, a tendency to recede from the earth instead of falling towards it, as ponderable bodies do. Such an assumption, however improbable in itself, would of course suffice for its immediate purpose; that is to say, of accounting for the increase in weight of a body by loss of phlogiston; but the explanation thus afforded took no account of the oxygen, which Lavoisier had shown to be abstracted from the air and added to the burning body. Accordingly, as experiments were multiplied, and it was shown that in all cases of combustion, the weight of the product was equal to the weights of the combining bodies taken together, the phlogistic theory gradually lost its hold on the minds of chemists, and was ultimately abandoned.

At the time of Lavoisier, attention was chiefly directed to combustions taking place in the air or in oxygen gas, and to the reduction of metallic oxides by hydrogen or carbon. Chlorine also, then called *oxymuriatic acid*, was supposed to contain oxygen; bromine and iodine were not known. Accordingly it was natural that oxygen should be regarded as essentially the supporter of combustion, the bodies which burned in it being called combustibles. Afterwards, when chlorine was shown to be an elementary substance, and when bromine and iodine were discovered, and metals, &c., were found to burn in their vapours, the term supporter of combustion was extended to all substances capable of forming vapours in which others can burn; thus, when copper-foil burns in sulphur vapour, the sulphur may be called the supporter, and the copper the combustible. But since the same substance may act sometimes as a combustible, sometimes as a so-called supporter,—*e. g.* sulphur as a combustible with oxygen, as a supporter with metals,—the distinction has gradually become obsolete.

The development of heat and light in combustion was attributed, on Stahl's theory, to the escape of phlogiston. The antiphlogistic theory, by dwelling chiefly on the ponderable substance produced by the combustion, and the relation between its weight and those of the combining bodies, tended rather to divert attention from the attendant phenomena of light and heat, and, indeed, was somewhat reproached by the adherents of the older theory for not rendering a sufficient account of those phenomena. Lavoisier attributed the heat accompanying combustion to the separation of the latent heat of the oxygen gas; and attempts have been made to extend this mode of explanation to all cases of chemical combination, in which gaseous or liquid substances pass to the solid state. This, however, will not account satisfactorily for the more intense evolution of heat in combustions and other combinations: for the latent heat of gases and liquids is small in comparison with such developments of heat. Moreover, in many instances, the combination is not attended with condensation; *e. g.* in the combustion of charcoal or sulphur in oxygen gas, and of hydrogen in chlorine gas; or again, gaseous products are formed from solid bodies, great heat being at the same time evolved, as in the explosion of nitre with charcoal, &c.

Neither can the heat of combustion be generally attributed to diminution of specific heat in the resulting compound; for in most cases the atoms of simple substances retain their original specific heat when they enter into combination (see ATOMIC WEIGHTS, i. 472, and HEAT). In other cases, on the contrary, combination is attended with an actual increase of specific heat, so that the result would be a production of cold, if heat were not developed from some other cause.

Thus, 1 lb. of hydrogen gas, of specific heat 3·293, combines, under the most violent evolution of heat, with 8 lbs. of oxygen of specific heat 0·236, producing 9 lbs. of water of specific heat 1·000, whereas calculation gives $\left(\frac{3·293 + 8 \,.\, 0·236}{9}\right) = 0·576$ as the mean of the two specific heats. If then water had a specific heat = 0·576, the quantity of sensible heat in the hydrogen and oxygen gases together would be exactly sufficient to bring the water formed to the same temperature as that of the gases themselves; but since the actual specific heat of water is 1·000, the quantity of sensible heat in the gases is not sufficient for this purpose; and if heat were not developed from some other cause during the combination of oxygen and hydrogen, the water produced would be much colder than the two gases before combination.

Berzelius, on reviewing these circumstances, justly concluded that all such explanations of the origin of fire are defective. He supposed that, in every chemical combination, there is a neutralisation of opposite electricities, and that this neutralisation produces the flame or fire, in the same way as it produces fire in the discharges of the Leyden phial and the voltaic battery, and in thunder. He admitted, however, that this hypothesis does not afford a satisfactory explanation of the union of the atoms after the discharge has taken place. (See CHEMICAL AFFINITY, i. 865.)

A more satisfactory explanation is that advanced by Sir Humphry Davy, viz. that the immediate cause of the phenomena of heat is motion, and that the laws of its communication are precisely the same as the laws of the communication of motion; that in fact, these phenomena are analogous to those of light, as expounded by the undulatory theory. On this principle we may explain the great heat produced by friction, and in explosions, such as those of oxide of chlorine, and chloride of nitrogen, cases in which heat and light are copiously displayed, at the same time that great enlargement of volume takes place, rendering the idea of the extrusion of a calorific fluid altogether inadmissible. Whenever the chemical forces which determine either composition or decomposition are energetically exercised, the phenomena of combustion, which are incandescence with a change of properties, are exhibited. In all cases, the heat and light depend on the same cause, and merely indicate the energy and rapidity of the reciprocal chemical attractions. No peculiar substance or phlogistic essence is necessary to the production of fire; but it is a general result of the actions of any bodies possessed of energetic chemical attractions or different electrical relations; and it is produced in all cases in which an intense and violent motion may be conceived to be communicated to the particles of bodies.

We now proceed to consider the circumstances which favour or retard combustion and determine the nature of flame, confining our attention chiefly to cases of combustion in the air. For the greater part of our knowledge on this subject we are indebted to the admirable researches of Sir Humphry Davy (Phil. Trans. 1817, pp. 45 and 77), which led him to the invention of the Miner's Safety-lamp. The subject may be treated under the following heads:—

1. The temperature and other conditions required to inflame different bodies.
2. The nature of flame and the relation between the light and heat which compose it.
3. The causes which modify and extinguish combustion.

The quantities of heat evolved in the combustion of different bodies will be more conveniently considered in the article HEAT (*q. v.*)

I. *Conditions of Inflammability.*

But few substances are capable of combining with *oxygen* at ordinary temperatures, and those which exhibit this capacity lose it at lower temperatures. The temperature required to bring about the combination of oxygen with any substance, the *burning point*, as it may be called, is different, not only for different substances, but even for the same substance, according as the combustion is to take place rapidly or slowly. Thus, phosphorus combines slowly with oxygen, or exhibits *slow combustion* at 25° C. (77° F.), but does not enter into rapid combustion till raised to 60° C. (140° F.) Charcoal likewise burns slowly below a red heat. Sulphur takes fire in the air at about 285° C. (550° F.) Most other elementary bodies require to be heated to redness before they take fire in the air or in oxygen gas. Several organo-metallic bodies, as zinc-methyl, cacodyl, and some of the antimonides of ethyl and methyl, take fire immediately on exposure to the air. Nitrogen cannot be made to unite with oxygen by elevation of temperature, except under peculiar circumstances; chlorine, bromine, and iodine not at all by heat, only by substitution.

Chlorine unites rapidly with hydrogen at ordinary temperatures, and under the influence of direct sunshine, produces a violent explosion. Many metals also burn when introduced into chlorine at ordinary temperatures. *Bromine* and *iodine* unite rapidly with phosphorus and with several metals, especially if in the finely divided state, at ordinary temperatures; but in a tube cooled with ice, phosphorus and iodine may be brought together without acting on each other.

Sulphur unites with many metals at a red heat, the combination being attended with vivid incandescence, *e.g.* with iron and copper.

The relative inflammability of different bodies in common air may be approximately estimated by fusing a series of globules of different sizes at the ends of thin iron wires, and lighting a number of very small flames of different substances, but all of the same size. A globule $\frac{1}{30}$ of an inch in diameter brought near an oil flame $\frac{1}{30}$ of an inch in diameter will, if cold, extinguish it at the distance of a diameter. The size of the globule required to extinguish the flame will afford a rough measure of the relative inflammability of the burning body. The combustibility of different gases may also be approximately measured by the sizes of the masses of heated bodies required to set them on fire. An iron wire $\frac{1}{40}$ of an inch thick at a cherry-red heat will inflame hydrogen, but not olefiant gas, which, however, is kindled by a wire $\frac{1}{8}$ of an inch thick at the same degree of heat. A wire $\frac{1}{500}$ of an inch thick must be heated to whiteness to inflame hydrogen, but it will kindle phosphoretted hydrogen at a low red heat. Carbonic oxide takes fire in the air by contact with an iron wire at a dull red heat; but the fire-damp of mines is not kindled by a wire $\frac{1}{40}$ of an inch thick heated even to whiteness. (Davy.)

Compression of the air does not appear to facilitate combustion, unless it takes place rapidly, and is consequently attended with considerable evolution of heat. Thénard, however, found that wood does not take fire in oxygen gas under the ordinary pressure at temperatures below 350° C., but under a pressure of 2·6 met. combustion begins at 252°. On the other hand, phosphorus in oxygen gas or common air exhibits slow combustion at a temperature which is lower in proportion as the gas or air is more rarefied; and a mixture of oxygen and phosphoretted hydrogen, which, under the ordinary atmospheric pressure, requires a temperature of 116·7° C. to inflame it, does not take fire at 118° when the density is increased to fifteen times its former amount; but if the mixture, contained in an inclined glass tube standing over mercury, be rarefied by setting the tube upright, combustion takes place at 20°. Döbereiner likewise found (J. pr. Chem. i. 114) that a mixture of equal measures of oxygen, hydrogen, and nitrogen gases contained in a detonating tube was always exploded by the electric spark, if the tube were open at the bottom, or merely closed with water; but not always when the tube was closed by a cork,—the compression appearing to offer an obstacle to the continuation of the combustion.

The combination of oxygen with inflammable gases and vapours is greatly facilitated by contact with *platinum* and certain other metals, the effect depending partly on the power possessed by the metal of condensing the gases on its surface or within its pores, if it be in the spongy or finely divided state, partly on a polarised condition of the molecules (see CONTACT-ACTION). When a clean plate or wire of platinum is immersed in a mixture of oxygen (or common air) and a combustible gas, a slow combustion takes place at first, by which the temperature of the solid body is raised,—and consequently, the process of combustion is not only sustained but actually accelerated; and at length the temperature of the solid body may be so much raised as to give rise to rapid combustion. The larger the surface of the metal, the more powerful is its action.

It was observed by Sir H. Davy that a mixture of oxygen gas or common air with hydrogen, carbonic oxide, olefiant gas, cyanogen, or vapour of hydrocyanic acid, alcohol, ether, rock-oil, or oil of turpentine, is brought into a state of slow combustion by contact with thin platinum foil or a spiral of platinum wire heated to a temperature short of redness,—that the heat thus developed brings the platinum to a state of bright ignition,—and that, with certain gases, rapid combustion at length ensues. He likewise found, as had been previously observed by Grotthus, that the mixture of oxygen and hydrogen gases heated not quite to redness in a glass tube, passed in a few minutes into the state of combination and formed water, without sensible evolution of light and heat. Erman showed that the platinum wire requires a temperature of only 50° to 51° C. in order to induce the combination of oxygen and hydrogen. E. Davy found that platinum-black (platinum in a state of division still finer than that of spongy platinum), moistened with alcohol, became incandescent in the air and induced combustion of the alcohol. Finally, Döbereiner discovered that freshly ignited spongy platinum (as it remains after ignition of ammonio-chloride of platinum) excites, even in the cold, first the slow, and then, under favourable circumstances, the rapid combustion of a mixture of hydrogen gas with oxygen or atmospheric air. It appears from the experiments of Döbereiner, Pleischl, Dulong, and Thénard, that this property is possessed (though in a less degree, so that in most cases the temperature must be raised, though never to the burning point) by other solid substances, both metallic and non-metallic, *e.g.* palladium, rhodium, iridium, osmium, gold, silver, cobalt, nickel, charcoal, pumice-stone, porcelain, glass, rock crystal, and fluor-spar.

These effects may be shown in either of the following ways:

1. Spongy platinum fastened to the end of a wire is suspended within a glass flask, which is then exhausted of air and filled with the mixture of oxygen and the combustible gas.—2. The gaseous mixture is contained in a vessel standing over mercury,

and the spongy platinum fastened to a wire is pushed up into it: or a piece of it is simply passed up by itself through the mercury into the gas. The platinum is best prepared for this purpose by forming a mixture of moistened clay and ammonio-chloride of platinum, or of sal-ammoniac and spongy platinum, into balls, and heating them gently: the balls thus prepared may be used several times.—3. The mixture of oxygen or air with the combustible gas is directed on the spongy platinum contained in a glass dish or a funnel.—4. The spongy platinum is attached to a fine platinum wire (for this purpose the platinum wire may be wound into a spiral, or a loose net may be made of it; and upon this a portion of ammonio-chloride of platinum, made into a thick paste with a small quantity of water, may be fastened, and then ignited); a stream of the combustible gas is then to be directed upon it: the gas is thus brought in contact with the platinum after first mixing with the air.—5. Fine platinum wire is wound from three to eight times in a spiral form round a thin glass rod or an iron wire, the turns of the spiral being kept very close together: it is then removed, and inserted by its lower extremity into the end of a glass tube, from which the combustible gas issues into the air;—or the lower turns of the spiral are fixed round the wick of a lamp fed with a combustible and volatile liquid, such as alcohol, ether, or a volatile oil; or again, the end of the wire is inserted into the middle of the wick or into a capillary tube into which the liquid rises. This arrangement serves for the *lamp without flame* or *glow-lamp* (i. 74). It is usual to set fire to the vapour, and let it burn till the platinum wire becomes red-hot; then, when the flame is blown out, the wire continues to glow.—6. A triangle of fine platinum foil is cemented by one of its corners into a thin glass rod, which serves for a handle, and held over the aperture (in some cases after being heated) from which the combustible gas issues into the air,—or else over a volatile liquid, such as alcohol or ether. The greater the purity of the ammonio-chloride, the more efficient is the spongy platinum prepared from it. As with platinum, so also with the other metals above named.

Effect of mechanical division.—Many finely divided substances are capable of burning at comparatively low temperatures, as shown by the following experiments:—When oxide of nickel, cobalt, or iron is reduced by hydrogen gas at a temperature of about 360° C., or not quite amounting to redness, or when oxalate of iron is heated in close vessels not quite to redness, whereby the iron is reduced, the metallic powder thus obtained burns with a glimmering light on being exposed to the air at ordinary temperatures. If the heat during the reduction be raised to redness, or if the metal reduced at a heat below redness be afterwards ignited in hydrogen gas, it will no longer exhibit spontaneous combustibility, possibly, because the metal when thus strongly heated agglomerates in denser masses: but if a quantity of alumina or glucina be mixed with the metallic oxide,—by mixing the solution with that of the salt of alumina or glucina, and precipitating by an alkali,—the metal, when reduced by hydrogen, even at a red heat (provided the heat has not been very intense), takes fire on exposure to the air, as readily as that which has been reduced at a lower temperature,—possibly, because the interposition of the earths, which are not reduced by the hydrogen, prevents the particles of metal from welding together. Copper reduced by hydrogen gas at a very moderate heat was likewise observed on one occasion to become covered, on exposure, with a film of oxide, without however taking fire. Iron reduced by hydrogen gas absorbs several times its volume of carbonic acid gas; it thereby loses its inflammability, which, however, it recovers by being again heated in hydrogen gas. This property of spontaneous inflammability may be explained in two different ways: 1. The metal reduced by hydrogen retains a portion of this gas enclosed among its particles; when exposed to the air, it induces combination between this substance and the oxygen of the air (after the manner of Döbereiner's process), and the great heat evolved in this combination causes the metal to take fire. Against this, however, it may be alleged that iron reduced from the oxalate cannot contain hydrogen gas enclosed amongst its particles (it may, however, contain carbonic oxide); and even when the metal is thrown into water, and the water driven off by evaporation, spontaneous combustion is still produced by contact of air.—2. The metal when exposed to the air absorbs the air mechanically, just as any porous body would do (and possibly it may absorb oxygen with peculiar avidity); and the heat developed by this mechanical absorption gives rise to the combustion. If the metal has been previously saturated with carbonic acid gas, of which perhaps it absorbs a larger quantity than of oxygen, it does not become heated by contact with the air (Magnus). Wöhler likewise found that intimate mixtures of charcoal and reduced metals often possess the property of taking fire at a red heat.

The spontaneous combustion of other porous substances, such as charcoal-powder or small coal, and especially of masses of tow, cotton, or rags saturated with oil, takes place in a similar manner. The substance absorbs and condenses the air within its pores; oxidation then commences immediately and raises the temperature, which again accelerates the oxidation; and thus the process goes on with continually increasing rapidity, till at length the mass bursts into flame. The low conducting power of such a porous mass greatly facilitates the combustion, by preventing the dissipation of the heat generated. Instances are known of olive oil igniting upon sawdust; of greasy rags from butter, heaped together, taking fire within a period of twenty-four hours; of the spontaneous combustion of tape-measures, which are covered with an oil-varnish, when heaped together; and even of an oil-skin umbrella put away in a damp state. The presence of moisture greatly promotes the spontaneous ignition of porous materials, such as hay or coal-dust, the water probably supplying oxygen to the combustible matter. (See Graham's *Report on the cause of the fire in the "Amazon."* Chem. Soc. Qu. J. v. 34.)

II. *Nature of Flame.*

The fire which accompanies the process of combustion appears either as *Glow* or *Incandescence*, when the burning body does not become gaseous before combustion, or as *Flame*, when the burning body is previously converted into gas or vapour. In the former case, the heat evolved at the surface of contact of the oxygen and the combustible body, charcoal or iron for example, heats the body and causes it to glow with various degrees of brightness, according to the temperature. Feebly glowing coals emit a dull red light (*cherry-red heat* or *dull red heat*); when more strongly heated, they emit a yellowish-red light (*bright* or *full red heat*): at still higher temperatures, a yellow light (*dull* or *commencing white heat*); then a yellowish, then a greenish, and lastly a bluish-white, intensely dazzling light (*bright*, *full*, or *dazzling white heat*).

When the combustible body is in the gaseous form, either originally or in consequence of the heat required to set it on fire, the mixture of this gas with the oxygen and the products of the combustion constitutes flame, which is, in fact, gaseous matter heated to incandescence. If the combustible gas or vapour, and the oxygen or air are uniformly mixed before ignition, the combustion takes the form of an explosion, combination taking place at once throughout the whole mass of gaseous matter, which consequently appears equally luminous throughout. A similar effect takes place when a combustible substance, such as sulphur or charcoal, is intimately mixed with a nitrate, chlorate, or other solid substance which readily gives up oxygen: if the temperature of such a mixture be raised to the burning point at one spot by friction, percussion, or the contact of a hot body, the ignition of the first few particles raises the temperature of the next, and then the action is propagated in an inappreciably short space of time throughout the whole mass, producing a sudden and violent evolution of gas, occupying many thousand times the volume of the original solid mixture. The noise attending the explosion arises from the violent concussion of the surrounding air produced by the sudden expansion of the burning gases.

But when the combustible gas or vapour issues from an orifice or a wick into the air, or into an atmosphere of oxygen, the combustion takes place gradually at the surface of contact of the two gases, and a flame is produced, consisting of an inner dark and less heated space filled with the combustible gas, and a glowing envelope marking the boundary at which the combustible gas and the oxygen come in contact and unite. That such is really the structure of flame may be shown by placing a piece of phosphorus on the wick of a burning spirit lamp, the phosphorus not taking fire till it is pushed outwards. If a piece of phosphorus be placed on a wooden support in the middle of a basin filled with alcohol, and the alcohol be set on fire, the phosphorus melts, but does not take fire till the alcohol is burnt away or extinguished, or till the flame is blown on one side, or air directed upon the phosphorus by means of the blowpipe. In a similar manner, a lighted candle will go out when placed in the midst of an alcohol flame.

The *brightness* or *illuminating power of flame* depends, not only on the degree of heat, but likewise on the presence or absence of solid particles which may act as radiant points. A flame containing no such particles emits but a feeble light, even if its temperature is the highest possible—the flame of hydrogen gas, for example. But in flames which do contain solid particles, the brightness increases with the temperature to which these particles are raised. Solid particles in a flame sometimes arise from the combination of the combustible body with oxygen, *e. g.* phosphoric acid or oxide of zinc in the combustion of phosphorus or zinc; sometimes, when the burning body is an organic hydrocarbon in the gaseous state, they consist of particles of carbon in the form of soot, separated in the interior of the flame by the heat of the burning envelope. A dull flame becomes brighter by the introduction of a solid body in a finely divided state.

The following substances give a *dull flame:* hydrogen gas, carbonic oxide gas, sulphur, selenium, arsenic, alcohol—and likewise coal-gas when it is mixed with a sufficient quantity of air to cause it to burn without deposition of soot: phosphorus also burns with a dull flame in chlorine gas, because the chloride of phosphorus, which is the product of the combustion, remains in the gaseous state (H. Davy). When a spiral of platinum wire or a piece of asbestos is held in either of these flames, or some powdered oxide of zinc thrown into it, the solid matter immediately becomes white, and emits a vivid light (H. Davy). Paper soaked in solution of chloride of calcium and burnt in the flame of a spirit lamp, leaves a white network of ashes, which, when held in the feeblest alcohol flame, emits a brilliant light. (Talbot, Phil. Mag. [3] iii. 114.)

If alcohol vapour be projected from one set of tubes, and oxygen gas from another set, upon a ball of quicklime, having a stem by which it is fastened to a wire, the alcohol burning in the oxygen gas heats the ball to the most dazzling whiteness; so that the light, when reflected by a concave mirror placed behind it, is plainly visible at the distance of 68 miles. Zirconia gives a light somewhat less powerful than that of lime; that produced by magnesia is only half as strong. (Drummond, Ed. J. of Sc. 5, 319.) By the oxy-hydrogen blowpipe (i. 613) lime is rendered much more brightly luminous than by alcohol and oxygen gas. Supposing the intensity of light of a wax candle = 1, that emitted by a cylinder of lime whose circumference is one-fifth of that of the flame of the candle, is equal to 153 when it is ignited by the oxy-hydrogen flame; to 76, in the flame of ether and oxygen; to 69, in that of alcohol and oxygen; and to 19, in that of coal-gas and oxygen. Unburnt chalk, white clay, and magnesia, give much less light than burnt chalk.

A *bright flame* is produced by the following bodies:—

1. Those which in combination with oxygen form a solid compound: phosphorus, potassium, antimony, bismuth, zinc, and most other metals. (Davy.)

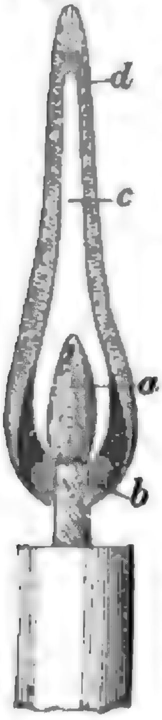
2. Compounds containing carbon, from which a portion of the carbon is separated in the form of soot, by the heat produced at the part where the combustion actually takes place, the separated carbon being first brought to a state of vivid incandescence, and subsequently burnt when it comes in contact with oxygen. This is the case with marsh-gas, olefiant gas, ether, volatile oils, fats, resins, &c. (H. Davy). The flame of alcohol may likewise be rendered bright by the presence of any substance which causes the carbon to separate from it. Thus, chlorine gas mixed with the flame of alcohol increases its luminosity, because, by combining with the hydrogen, it causes a deposition of solid carbon. Vapour of dioxide of osmium likewise gives luminosity to the flame of alcohol, by giving up osmium and separating carbon from the alcohol. To produce this effect, a piece of osmium is laid on the edge of a piece of platinum-foil, and the foil held over the alcohol flame, so that the osmium may burn, and the vapours of the oxide may mix with the vapour of alcohol (Berzelius). The flame of hydrogen or marsh-gas may be rendered bright by passing the gas through coal-tar naphtha, rock-oil, or some other volatile hydrocarbon, the vapour of which then mixes with the gas and brightens the flame by the separation of its carbon.

On the contrary, by mixing a jet of carbonaceous gas or vapour with oxygen, as in Bunsen's gas-burner, in which air is admitted just above the point where the stream of gas enters the burner, so that the gas and air become well mixed before they reach the orifice, a complete combustion of the carbon is obtained, and only gaseous products are formed, the result being a very hot smokeless flame of feeble luminosity. A similar flame is obtained by laying a sheet of wire-gauze on the top of the chimney of an Argand gas-burner, and setting fire to the gas above the gauze. The gas then becomes well mixed with air in passing up the chimney, and the carbon is completely burned as before.

The more slowly a carbonaceous substance is burned, the greater is the quantity of carbon separated from it; the brightness of the flame is, however, diminished in the same proportion, because the particles of carbon are less strongly heated. On the contrary, the quicker the combustion, the smaller is the quantity of carbon separated; but the temperature to which it is raised is so much the higher, and consequently it emits a brighter light.

The flame of highly carbonised substances, such as a wax or tallow candle, consists of four parts, as represented in fig. 129. *a*, a *dark inner cone*, surrounding the wick, and consisting of the combustible gas and vapour issuing therefrom, mixed with atmospheric nitrogen and the products of combustion, viz. water and the oxides of carbon; *b*, a *light blue zone* at the bottom of the flame, and reaching a little way up the inner cone. In this part, the combustible matter of the inner cone comes in contact with the oxygen of the air not yet rarefied by the heat, and is completely burned just as in the inner blowpipe-flame (i. 613), producing a light of the same bright blue colour. *c*, a *highly luminous cone* surrounding the dark inner cone. In this part, the supply of oxygen is not sufficient, excepting at the outer surface, for the complete combustion of the carbon, which is therefore separated in minute solid particles, and these being strongly heated by the combustion, become highly incandescent: if a cold body be introduced into the flame, these particles of carbon are deposited as soot. *d*, the *mantle*, a feebly luminous, yellowish cone surrounding the entire flame, excepting just at the bottom, and consisting of atmospheric air heated to incandescence, and mixed with the final products of the combustion. This part of the flame is often confounded with the blue zone, from which, however, it is really distinct. The best mode of observing it is to cut out a piece of cardboard of nearly the shape of the flame, and hold it at such a distance from the eye as just to hide the luminous cone.

Fig. 129.



The flame of an Argand lamp, which is supplied with air within as well as without, may be compared to the flame of an ordinary lamp or candle flattened out, and then bent into a cylinder. It contains the same parts as the conical flame, but from the form of the wick, the dark zone is necessarily very thin.

The composition of the flame of wax and tallow burning from a wick has been accurately investigated by Hilgard (Ann. Ch. Pharm. xcii. 129; Jahresb. f. Chem. 1854, p. 287). The lamp used in the experiments consisted of a shallow cylinder containing the fuel, and having in its axis a glass tube, over the upper end of which the cylindrical wick was drawn. Through this tube, which was capable of sliding up and down, a narrower tube connected at its lower end with an aspirator passed upwards into the flame. This narrow tube was attached to the outer tube by means of a caoutchouc connecter, in such a manner that no air could pass through the wide tube into the flame. By this arrangement, the gases could be collected at any required height in the flame; they then passed through a series of condensers, and finally into a glass tube in which they were sealed up for examination.

In the following table, the composition of the gases at different heights (in millimetres) above (+) and below (−) the edge of the wick is given in percentages by volume; the symbol C^2H^4 includes ethylene and the hydrocarbons polymeric with it. X denotes the weight of liquid and solid matter condensed from a litre of the flame-gas.

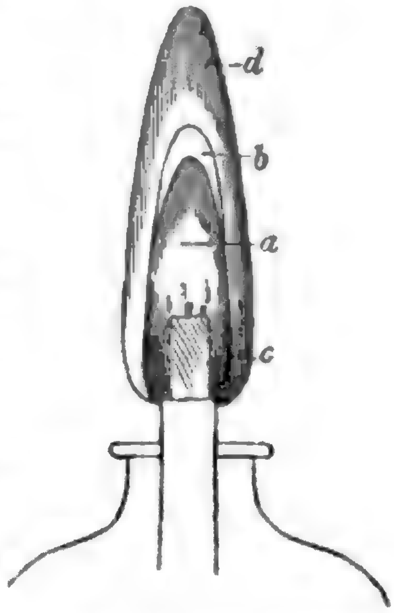
The large quantity of nitrogen in the interior of the flame arose from the circumstance, that the air entered the flame in a nearly horizontal direction, especially at the lower part. The proportion of nitrogen is a minimum at 2mm. above the edge of the wick, chiefly because the greater heat and increasing amount of decomposition in this part of the flame produce a larger amount of permanent gases. The quantity of carbonic anhydride is nearly inversely proportional to that of the hydrocarbons, C^nH^{2n}. When the nitrogen is deducted, the sums of the amounts of carbonic anhydride, ethylene, &c., and carbonic oxide are nearly constant. The total quantity of these three gases appears to alter but slightly from the bottom of the flame to a height of 7mm. or 8mm; at a greater height, it appears to increase, in consequence of the excess of the products of oxidation.

The inner cone of the flame contains the unburnt gases issuing from the wick, mixed with atmospheric nitrogen and carbonic oxide, carbonic acid, and water, produced by the combustion going on in the outer cone, but *no free oxygen*, that gas being completely converted into the products just mentioned in passing through the outer cone. The composition of the gases at different heights of the flame is determined by the natural action of the combustible gases in the inner cone and the oxidised products proceeding from the outer part.

The luminous envelope surrounding the inner cone varies in composition from without inwards, the outer portion containing a considerable quantity of free oxygen which gradually diminishes as it penetrates inwards. The thickness of the luminous envelope increases towards the upper part of the flame, because this portion contains the oxidised products ascending from below, in addition to those directly formed there, so that the proportion of combustible gases in the upper part of the flame is less, the combustion is slower, and the oxygen of the air can penetrate to a greater depth; hence the luminous envelope diminishes in brightness and increases in thickness from below upwards, and near the apex it presents the appearance of a solid cone. The reducing part of the flame is at the surface of contact of the inner cone and the luminous envelope.

The flames of combustible bodies which do not undergo the decompositions above described, differ considerably in composition from those of wax or tallow. The luminous cone is often absent, more rarely the mantle: the inner cone is of course always present, and the blue zone is almost always represented by the part where the still undiluted combustible gas comes in contact, at a comparatively low temperature, with air containing its full amount of oxygen. The flame of **carbonic oxide** exhibits a distinct dark cone (consisting of unburnt gas), a dark blue zone, and a yellowish-red mantle not sharply defined from the surrounding air. The flame of **sulphur** has a blue zone at the bottom and a violet-reddish mantle, the colour with which sulphur-vapour burns when previously strongly heated. In the **alcohol-flame** (*fig.* 130) the inner cone *a* is very large, in consequence of the volatility of the combustible substance: the luminous cone *b* is small, because there is but little carbon separated; and the mantle *d* appears very much developed, because the eye is not dazzled by a bright luminous cone.

Fig. 130.



The composition of the flame of ***coal-gas*** has been examined by **Landolt** (Pogg. Ann. xcix. 389), by a method similar to that above described for the wax and tallow flames. The gas, properly purified from carbonic acid, oxygen, and aqueous vapour, was passed, under pressure of a column of water, 17 Paris lines high, into a brass box, having at the top a circular aperture 7mm. wide, and a tube of nearly the same diameter passing tightly through the bottom, and terminating on a level with the circular opening, so that the gas was made to issue through the narrow ring-shaped slit thus formed. A tube connected with an aspirator passed up through the brass tube into the flame, as in Hilgard's experiments. The flame was protected from draughts of air by a glass cylinder suspended over it and reaching to within 20mm. of the burner; it was from 95 to 100mm. high when burning freely, and from 85 to 95mm. while gas was being drawn out of it. The following table gives the composition of the purified coal-gas (L) introduced into the burner, and that of the flame-gas, at various heights, D mm., above the ring-shaped aperture, in percentages by volume (F).

Composition of Coal-gas flame.

D . . .	0mm.		10mm.		20mm.		30mm.		40mm.		50mm.

Carbonic acid .	—	1·74	0·58	1·95	0·37	4·11	0·37	4·81	—	5·62	—	7·01
Water . .	—	7·48	—	9·66	—	15·79	—	16·87	—	17·19	—	16·39

From these results, Landolt has calculated the proportions of coal-gas and air which by their mutual action form the several parts of the flame-gas. The results are somewhat discordant, according as the carbon, hydrogen, or nitrogen is taken as the basis of the calculation; but the most probable results are given in the following table, in which A denotes the volumes of atmospheric air which have mixed with 100 vols. coal-gas to produce the flame-gas at the several heights, D, indicated in the first line. 100 + A = M volumes of this unburnt gaseous mixture yield, after combustion, V volumes of flame-gas. The composition of the M volumes of unburnt gaseous mixture and of the V volumes of flame-gas produced by their combustion are given in the lower part of the table.

Composition of Coal-gas flame.

The sudden increase in the quantity of air mixing with the combustible gas between the heights of 10 and 20mm., is attributed by Landolt to the effect of the glass cylinder. The proportion of carbonic acid does not increase towards the upper part of the flame so rapidly as might be expected, probably on account of the reduction of that gas to carbonic oxide by the the ignited carbon in the flame; hence also the sudden increase in the proportion of carbonic oxide between the heights of 30 and 40mm. The quantities of the several combustible gases in the flame diminish from below upwards, at rates proportional to their combustibility. From 0 to 20mm. the decrease of the hydrogen is the most rapid; the increase in the proportion of this gas in the flame above the height of 20mm. is probably due to the reducing action of the ignited carbon in the aqueous vapour. The marsh-gas diminishes more slowly, and the heavy hydrocarbons still more slowly, the latter indeed remaining nearly unaltered in the flame up to 40mm., and burning only in the higher part.

The *brightest light* was found to be given out by the part of the flame a little above the top of the dark cone. In a gas-flame 100mm. high, in which the dark cone reached to about 65mm., the highest part was at 70mm., and supposing the brightness of this part = 100, that of the other parts of the flame was found to be as follows:

	mm.	mm.	mm.	mm.	mm.	mm.
Height above burner . .	80	70	60	50	40	30
Brightness at the edge . .	66	100	77	47	20	4
Brightness in the middle .	66	100	59	24	5	—

The *size of a flame* is greater in proportion as a larger quantity of oxygen is required to consume a given volume of the rising combustible gas, and also as the surrounding oxygen is mixed or combined to a greater extent with foreign gases; for, in that case, the combustible gas must present a larger circumference, and a greater number of points of contact to the oxygen, in order that the latter may be consumed as fast as it is supplied.

When different combustible gases are made to flow from a jet, in streams of given strength, into oxygen gas and mixtures containing it, the following effects are observed: Hydrogen gas gives a much smaller flame than olefiant gas (1 volume of hydrogen requires half a volume of oxygen, and 1 volume of olefiant gas requires 3 volumes of oxygen to burn it). Hydrogen gas mixed with nitrogen gives a still smaller flame than pure hydrogen. The flame of hydrogen gas in oxygen is smaller than that of the same gas in air; but there is this anomaly observed, that hydrogen gives a smaller flame in air than it does in chlorine or nitrous oxide gas,—although one volume of hydrogen gas requires 2·4 volumes of air and only 1 volume of chlorine or of nitrous oxide gas. This peculiarity is probably due to the different degrees of diffusibility of the gases through each other.

The *colour of the flame* depends partly on its temperature, partly on the nature of the substances contained in it.

Cold carbonic oxide gas gives a blue flame in burning; but if it has previously been heated, it gives a yellowish red flame. Hydrogen and other gases, which in burning evolve more heat than is evolved by carbonic oxide, exhibit a yellowish red flame even when set on fire in the cold. But when hydrogen gas issues from a fine jet (as in Marsh's apparatus) against a porcelain slab held close in front of it, a pale green flame is produced,—possibly in consequence of the cooling action of the porcelain. The blue flame at the lower part of the flame of a candle likewise indicates a comparatively low temperature. It is remarkable that in the glowing combustion of solid bodies the colours exhibit exactly the opposite relation (p. 1094).

The addition of boric acid, or of a metallic chloride and oil of vitriol, to alcohol, gives the flame a green colour—or, when it is more strongly heated, it turns yellow. Chloride of strontium or chloride of calcium colours the flame of alcohol red; chloride of barium, or common salt, colours it yellow; protochloride of copper gives it a bright red colour, with green and blue edges. Copper covered with oxide or sulphide (but not clean copper), held in the flame of alcohol, colours it green. The flames of other burning bodies undergo similar alterations. Chloride of strontium reddens the flame of hydrogen, marsh-gas, and olefiant gas, as also that of a candle—but only so long as the salt itself remains moist; on the flame of sulphur it has no effect. In all these cases, a portion of the added substance undoubtedly volatilises: but whether it volatilises undecomposed, so that the colour of the flame is altered merely by the presence of boracic acid, chloride of strontium, chloride of copper, &c., or whether decomposition takes place, so that boron, strontium, calcium, barium, or copper is introduced into the flame in the reduced state, is there burnt, and thereby produces a different colour—is a question not yet decided. Davy suggested the latter explanation.

Respecting the prismatic spectra produced by flames in which various salts, &c. are ignited, see ANALYSIS (i. 214), also LIGHT.

In ordinary flames, the combustible gas occupies the interior, and is surrounded by atmospheric air or oxygen gas. But the combustion may likewise be sustained by directing a stream of oxygen gas, air, &c., into a vessel filled with the combustible gas. The interior dark part of the flame then consists of oxygen gas; and this gas seems, as it were, to burn in the combustible gas. In this manner, oxygen gas (and also chlorine) may be made to burn in hydrogen; likewise oxygen gas, common air, vapour of pernitric oxide (or chlorine gas, with large deposition of soot) in olefiant gas. To produce this effect, a stoppered bell-jar standing over water is filled with olefiant gas, the stopper removed, the gas set on fire, and the oxygen tube, which is fitted into a cork, plunged into the olefiant gas, the cork serving to close the aperture. Or a quantity of chlorate of potassium, contained in a small basin suspended from the cork, may be heated till it evolves oxygen gas, and then plunged into the olefiant gas previously set on fire at the mouth of the jar: the combustion then goes on, producing a beautiful light, the colour of which may be variously modified by the addition of nitrate of sodium, strontium, or copper (Kemp, J. Pharm. xx. 413; also J. pr. Chem. iii. 44).

The flame of oxygen in hydrogen gas is green, even when both gases are quite pure: that of oxygen in marsh-gas is yellow. The first-mentioned flame is much larger than the other, because a measure of oxygen gas requires two measures of hydrogen, and only half a measure of marsh-gas (Hess, Pogg. Ann. xliv. 336; also J. pr. Chem. xiii. 516).

The flame is smaller when oxygen or nitrous oxide gas, or vapour of pernitric oxide, or chlorine gas is made to pass into hydrogen gas, than in the contrary case; according to what was said on p. 1098, the contrary might have been expected. A much smaller flame is produced when oxygen passes into olefiant gas than when it passes into hydrogen. With olefiant gas, the flame is dark within; then follows a brilliant envelope, hot enough to melt platinum; then, towards the outside, a dark yellow flame, lengthening above and containing soot, the greater part of which remains unburnt. When oxygen gas is blown into boiling sulphur, a yellow flame is produced, dark within, red on the outside and at the apex: air gives a smaller flame than oxygen, dark within, blue without, and red at the apex (Waldie, Phil. Mag. [3] xiii. 86).

The *Blow-pipe flame* is of the same character as those just mentioned, inasmuch as the air is blown into the middle of the ascending combustible vapour. The strongest heat exists at that part of the flame where the dark cone of injected air terminates in a bluish vertex, and the burning envelope which surrounds it concentrates itself upon a single point (i. 611).

III. *Causes which modify and extinguish Combustion.*

When the slow or rapid combination of a body with oxygen has once been set up by elevation of temperature, the continuance of this combination, after the supply of heat from without has been withdrawn, depends in general on the following condition: — Whether the quantity of heat, which the body in combining with oxygen evolves in a given time, is equal to that which, in the same time, is carried away by surrounding bodies; and consequently, whether the body remains at the temperature necessary for combustion; — and in particular: 1. On the difference between the temperature at which the body will combine with oxygen, rapidly or slowly, and the external temperature; 2. On the quantity of heat which it evolves in burning; 3. On the rarefaction or condensation of the oxygen gas; 4. On the greater or smaller admixture of foreign gaseous bodies not contributing towards the combustion; 5. On the presence of liquid or solid heat-conducting bodies.

1. Iron and diamond require a white heat to make them burn rapidly: hence, when they are heated in the air till they begin to burn, the combustion ceases as soon as the access of heat from without is discontinued, whereas sulphur, and other easily inflammable bodies, continue to burn.

2. Carbonic oxide gas, which is as easily inflammable as hydrogen, does not exhibit rapid combustion after it has been rarefied to about one-fourth of its ordinary density, because it evolves less heat during combustion. (H. Davy.)

3. A certain degree of rarefaction prevents the continuance of combustion; because combination, and therefore, also, development of heat, is retarded by it. Detonating gas (a mixture of two measures of hydrogen gas and one of oxygen), when rarefied to $\frac{1}{18}$ of its ordinary density, no longer explodes by the electric spark (H. Davy). Hydrogen gas, mixed with air in the right proportion, will not take fire under an external pressure of five inches (Grotthuss). Hydrogen gas issuing from a jet into the air exhibits rapid combustion under a fourfold rarefaction of the air, burning even with a larger flame than before, but is extinguished when the density is reduced to between $\frac{1}{5}$ and $\frac{1}{6}$ of its ordinary amount.

The burning vapour of alcohol, ether, or wax, is extinguished, under these circumstances, by a five or sixfold rarefaction; sulphuretted hydrogen by a sevenfold rarefaction of the air. Sulphur continues to exhibit rapid combustion, even when the air is rarefied fifteen times; phosphorus, when the density is reduced to $\frac{1}{60}$; while the easily inflammable variety of phosphoretted hydrogen gas produces a flashing light, even in the best vacuum that can be made with the air-pump. Vapour of ether, in air rarefied thirty times, still produces a feeble flame on the introduction of a red-hot iron. Slow combustion on the surface of platinum is exhibited by marsh-gas, down to a fourfold rarefaction of the air; by carbonic oxide, to sixfold; by vapour of alcohol, ether, or wax, to eightfold; by olefiant gas, to ten or elevenfold; by hydrogen gas, to thirteenfold; and by vapour of sulphur, down to twentyfold rarefaction of the air. By elevation of temperature, the limits of inflammability are still further extended; so that detonating gas rarefied eighteen times, and heated to redness, exhibits a light as if from combustion, on the passage of an electric spark. (H. Davy.)

Within certain limits, however, the rate of combustion is independent of the density of the surrounding atmosphere. Frankland found that a stearin candle burned away at the same rate on the summit of Mont Blanc and in the valley of Chamounix. The brightness of the flame is, however, greatly diminished by rarefaction of the air. A coal-gas flame, burning in artificially rarefied atmospheres, exhibited an average decrease of illuminating power amounting to about 5·1 per cent. for each diminution of 1 inch of mercurial pressure. (Proc. Roy. Soc. xi. 137.) See FLAME.

4. Foreign gaseous bodies, which contribute nothing to combustion, absorb a portion of the heat generated by the combination, and reduce the temperature below the burning point, the rapidity of their action being proportional to their quantity, mobility, and capacity for heat. Not only do bodies in general burn more rapidly in oxygen gas than in atmospheric air, which contains only one volume of oxygen to four of nitrogen; but iron and diamond, which, when once set on fire, continue to burn in oxygen gas, are immediately extinguished in atmospheric air. In air four or five times compressed — which, therefore, contains one volume of oxygen gas — candles, hydrogen gas, sulphur, charcoal, and iron, do not, in consequence of the abstraction of heat by the nitrogen, burn more rapidly than they would in uncompressed air, to which $\frac{1}{5}$ of a volume of oxygen had been added. One volume of detonating gas loses its power of taking fire by the electric spark, if there be added to it $\frac{1}{2}$ a volume of olefiant gas, $\frac{2}{3}$ of a volume of fluoride of silicium, 1 volume of marsh-gas, 2 volumes of sulphydric or hydrochloric acid gas, 8 volumes of hydrogen in excess, 9 volumes of oxygen in excess, or 11 volumes of carbonic oxide: 5 measures of aqueous vapour do not destroy the inflammability of 1 measure of detonating gas (H. Davy). According to

Humboldt and **Gay-Lussac** (Gilb. Ann. xx. 49), the inflammability of one volume of detonating gas is destroyed by the admixture of 5 volumes of oxygen, or 4·7 volumes of hydrogen gas. Marsh-gas is no longer inflammable by the electric spark, when it is mixed with 11 measures of oxygen instead of the 2 measures which it actually requires to combine with it (**H. Davy**). Coal gas burns continuously in a mixture of 1 measure of oxygen and 7 of nitrogen, but is extinguished when the quantity of the latter amounts to 8 measures; it burns in a mixture of 1 measure of oxygen with 3, but not with 4 measures of hydrochloric acid gas; with 2⅓, but not with 3 measures of carbonic acid: with 2, but not with 2½ measures of fluoride of silicium. The greater the density of the inactive gas, the smaller is the quantity which suffices to stop the combustion; because the combustible gas diffuses itself more readily through a heavy than through a light gas, and therefore cools down the faster (**Waldie**). A lighted candle is extinguished in air to which ⅛ of its volume of hydrochloric acid gas, or $\frac{1}{16}$ of fluoride of silicium, has been added. When combustible bodies burn in a confined space, the relative quantity of nitrogen, &c. becomes increased, partly by consumption of oxygen, partly by formation of gaseous products of combustion, such as carbonic acid, sulphurous acid, &c.; and thus the combustion is brought to an end. In one and the same limited space, a candle goes out first, then hydrogen gas, then sulphur; while the slow combustion of phosphorus will go on as long as the smallest quantity of oxygen remains. (**H. Davy**.)

5. Solid burning bodies are extinguished when laid on good-conducting supports, *e. g.* glowing coals on considerable masses of metal.—A mixture of a combustible gas and oxygen will not take fire in very narrow tubes, because their sides cool down too quickly: this is the principle of the oxy-hydrogen blow-pipe (i. 616). From the same cause, the flame of a mixture of combustible gases and common air is often unable to pass through the meshes of wire-gauze: the passage of the flame takes place, however, with greater facility, the lower the temperature at which the gas takes fire, the greater the heat evolved by its combustion, the more quickly it is forced through the apertures by pressure or draught, the wider the meshes, the smaller the mass and specific heat of the metal of which the gauze is made, and the higher its temperature. Above a certain temperature, all flames pass through it. The flame of a cotton thread may be extinguished by holding over it, even at some distance, a ring of fine iron wire, or a thicker ring of glass (**Davy**). On this impenetrability of wire-gauze by the flame of light carburetted hydrogen gas in coal-mines, is based the *Safety-lamp* of Sir H. Davy, which consists essentially of a common oil-lamp having its flame surrounded by a cylinder of wire-gauze. When this lamp is taken to a part of the mine containing an explosive mixture of gas and air, the interior of the cylinder becomes filled with a blue flame; but this flame is not communicated to the explosive mixture outside, because it is cooled down below the burning temperature in its passage through the meshes of the gauze. (See the article SAFETY LAMP, in *Ure's Dictionary of Arts, Manufactures, and Mines*, iii. 612; also *Ronald's and Richardson's Chemical Technology*, i. [2] 511.)

The same principle is applied in many elegant contrivances now in use in chemical laboratories for burning a mixture of gas and air, so as to produce a hot smokeless flame (p. 1095), the mixture of gas and air being made to pass through a sheet of wire gauze, and set on fire at the other side, so that the flame cannot extend to the orifice whence the gas issues.

Motion of the air, produced by draught or by the bellows, accelerates combustion and increases the intensity of the heat, by continually bringing fresh portions of air in contact with the burning body. Very rapid motion of the air may however extinguish combustion, either by the cooling—if the quantity of air supplied in a given time is such that the burning body cannot in the same time consume the whole of its oxygen; or by blowing the burning vapour away from its source, so that the flame can no longer communicate with the fresh matter which issues.

Fire-extinguishing substances act either by cooling, as water does,—or by covering the burning body and thereby impeding the access of air—as when a rug or other not easily combustible body is thrown on a mass of light burning materials, or when a fire is choked with earth or ashes;—or lastly by surrounding the burning mass with an atmosphere not containing oxygen. This is the principle of *Phillips's Fire-annihilator*, in which a mixture of 20 pts. charcoal, 60 pts. saltpetre, and 5 pts. gypsum, is set on fire by means of chlorate of potash, sugar, and sulphuric acid, the heat produced by the combustion being made at the same time to convert into vapour a quantity of water contained in the apparatus. The result is the instantaneous production of a large quantity of steam, carbonic acid and other inactive gases, which can be at once directed on the burning mass. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, ii. 212.)

With regard to the efficiency of steam in extinguishing fires, Mr. Graham observes in his "Report on the fire in the Amazon," already quoted (p. 1094), that "steam can only be said to be efficient in extinguishing flame, or a blaze from light objects, and is not to be relied on beyond an early stage of a fire. Upon a mass of red-hot cinders, the extinguishing effect of steam is insensible." The same is probably true with regard to carbonic acid, nitrogen, and other gases.

Method of diminishing the inflammability of light fabrics.—Much attention has lately been devoted to the problem of rendering muslin and other light fabrics non-inflammable, with the view of preventing the terrible accidents, which so frequently arise from ladies' dresses coming in contact with the flame of a candle or the fire in a grate. This object is attained by steeping the fabric in a saline solution, and then drying it in the ordinary way. The fibre is thereby surrounded with a crust of incombustible matter, which prevents it from taking fire by momentary contact with a burning body, and causes it, even if held in a flame, to burn with a slow smouldering combustion, without bursting into flame.

Almost any salt will produce this effect, but the greater number are unfit for application to articles of dress, because they injure the texture, rendering the fabric harsh, and destroying all its beauty. The salt which is found to answer most completely all the required conditions, is the *neutral tungstate of sodium.* Muslin steeped in a solution containing 20 per cent. of this salt is perfectly non-inflammable when dry, and the saline film left on its surface is smooth and of a fatty appearance like talc, and therefore does not interfere with the process of ironing, but allows the hot iron to pass smoothly over the surface. The non-fulfilment of this latter condition completely prevents the use of many other salts—such as sulphate and phosphate of ammonium, which are otherwise efficacious in destroying inflammability—for all fabrics which have to be washed and ironed.

The use of the tungstate of sodium for this purpose offers but one difficulty, viz. the formation of an acid tungstate of little solubility. This inconvenience may, however, be obviated by the addition of a small quantity of phosphoric acid or phosphate of sodium. The best way of preparing a solution of minimum strength for the purpose, is to dilute a concentrated solution of the neutral tungstate with water to 28° Twaddell, and then add 3 per cent. of phosphate of sodium. The solution is found to keep, and to answer its purpose well; it is now constantly used in Her Majesty's laundry (Versmann and Oppenheim, *Communication read before the British Association at Aberdeen*, 15th Sept. 1859; Pharm. J. Trans. [2] i. 385). The use of phosphate of ammonium for preserving light fabrics from ignition was proposed, many years ago, by Gay-Lussac.

COMENAMETHANE. Syn. with Comenamate of Ethyl.

COMENAMIC ACID, $C^6H^5NO^4 + 2H^2O = \left.\begin{matrix} N.H^2.(C^6H^2O^3)'' \\ H \end{matrix}\right\} O + 2H^2O$. (How, Ed. Phil. Trans. xx. [2] 225; Ann. Ch. Pharm. lxxx. 65.)—This acid is produced by the dehydration of acid comenate of ammonium, $C^6H^3(NH^4)O^5 - H^2O = C^6H^5NO^4$. It may be prepared by heating the salt to 199° C. in a sealed tube, and precipitating the aqueous extract with hydrochloric acid; or better, by boiling aqueous comenic acid with excess of ammonia till nearly all the ammonia is expelled, collecting on a filter the grey argillaceous sediment of comenamate of ammonium and colouring matter, and dissolving it in hot water; decomposing the solution with hydrochloric acid not in excess; and purifying the precipitated dark brown scales of impure comenamic acid by repeated crystallisation from hot water, and treatment with animal charcoal free from iron. The crystals contain 2 atoms water (18·81 per cent.), and give it off at 100° C. They dissolve sparingly in cold, more freely in hot water, forming a solution which reddens litmus strongly. The acid dissolves in boiling alcohol of ordinary strength, but is nearly insoluble in boiling absolute alcohol.

The acid is decomposed by boiling with *potash*, yielding ammonia and comenate of potassium. It dissolves readily in *hydrochloric acid* and other strong mineral acids, and is precipitated therefrom by ammonia in quantity rather less than sufficient for saturation, as comenamate of ammonium.

Comenamic acid is monobasic, the normal salts being $C^6(H^4M)NO^4$. There are also several basic salts. The *ammonium-salt*, $C^6H^4(NH^4)NO^4$ forms small grains made up of delicate needles nearly insoluble in cold water; their solution reddens litmus. The *potassium-* and *sodium-salts* crystallise readily and redden litmus. The normal *barium-salt*, $C^6H^4BaNO^4$, obtained by mixing a solution of the crystallised ammonium-salt with chloride of barium, forms crystals with 1 at. water, which redden litmus. A *basic barium-salt*, $C^6H^4BaNO^4.BaHO + \frac{1}{2}H^2O$, is formed, by mixing chloride of barium with an ammoniacal solution of comenamate of ammonium, as a white heavy precipitate, which gives off its water (2·83 per cent.) at 100° C. The aqueous acid left in contact with carbonate of barium forms the normal or the basic salt according to the relative quantities. With *lime*, it forms two salts of similar constitution.

The ammonium-salt forms, with acetate of *lead*, a heavy insoluble precipitate.

Comenamic acid imparts to *ferric salts* a deep purple colouring, which is destroyed by mineral acids, but reproduced by water.

The crystallised ammonium-salt forms a grey precipitate with sulphate of *copper*.

The ammonium-salt super-saturated with ammonia forms, with nitrate of *silver*, a yellowish flocculent, quickly blackening precipitate; and the crystallised ammonium-salt forms a white gelatinous precipitate, which is partially decomposed by boiling water.

Comenamate of Ethyl, *Comenamic ether*, *Comenamethane*, $C^8H^9NO^4 = C^6H^4(C^2H^5)NO^4$. (How. Ed. M. Phil. J. i. 212.)—When a solution of comenamic acid in absolute alcohol is treated with dry hydrochloric acid gas, and the liquid subsequently evaporated, there remains an oil which dries up at 100° C. to a solid mass, and when dissolved in alcohol, yields a *hydrochlorate of comenamic ether*, $C^8H^9NO^4.HCl + H^2O$; and on treating this compound with oxide of silver, or with ammonia (not in excess), comenamic ether is obtained in needle-shaped crystals containing 1 at. water, which they give off at 100° C., leaving the anhydrous ether.—When the solid mass above mentioned is treated with water, comenamic acid remains undissolved, and another portion of that acid separates as a crystalline powder from the solution, which contains hydrochloric acid.

The ether is neutral; melts to a yellow liquid when heated; is not altered by ammonia in the cold; and is converted by nitric acid into oxalate of ammonia. It dissolves sparingly in cold *water*, readily in hot water and in *mineral acids*, sparingly in *absolute alcohol*.

A compound of this ether with *hydriodic acid* is obtained by heating iodide of ethyl with a solution of comenamic acid in absolute alcohol to 150° C., in sealed tubes.

COMENIC ACID. $C^6H^4O^5 = \left.\begin{matrix}(C^6H^2O^3)'' \\ H^2\end{matrix}\right\} O^2$, or $C^{12}H^4O^{10} = C^{12}H^2O^8.2HO$. *Parameconic acid*, *Anhydrous Meconic acid*.—(Robiquet, Ann. Ch. Phys. [2] li. 326; liii. 428. Liebig, Ann. Ch. Pharm. vii. 237; xxvi. 116. Stenhouse, Phil. Mag. [3] xxv. 196. H. How, Ed. Phil. Trans. xx. [2] 225. Gm. xi. 328. Gerh. ii. 182.)

Comenic acid was discovered in 1832, by Robiquet, who at first regarded it as anhydrous meconic acid; it was afterwards recognised as a distinct acid by Liebig, who first observed the formation of carbonic acid which accompanies the conversion of meconic into comenic acid. It is produced: 1. By heating meconic acid to temperatures between 120° and 220° C., the change being attended with evolution of carbonic anhydride:

$$C^7H^4O^7 = C^6H^4O^5 + CO^2.$$

2. By continued boiling of meconic acid dissolved in water or in hydrochloric acid, likewise with evolution of carbonic acid. (Robiquet.)

Preparation.—Meconic acid or its potassium or barium-salt, is boiled with a strong mineral acid; or meconate of calcium is boiled with highly concentrated hydrochloric acid (Stenhouse); or acid meconate of potassium, produced by treating crude neutral meconate of calcium with very dilute hydrochloric acid, is heated with as much strong hydrochloric acid as is required to dissolve it (How), and the solution is left to crystallise. When the mere aqueous solution of the acid is boiled, too large a quantity of brown secondary product is formed. (Robiquet, Liebig.)

To purify the product, the still reddish crystals are dissolved in a slight excess of hot concentrated potash; the solution is filtered hot to separate a small quantity of lime; the white nodules which form on cooling are washed with a small quantity of cold water, till the strongly coloured mother-liquor is removed, then boiled with excess of hydrochloric acid; and the comenic acid which separates on cooling is freed from hydrochloric acid by two or three recrystallisations from water. The still remaining tinge of red may be removed by treatment with animal charcoal (Stenhouse). Or, the impure acid is dissolved in a quantity of boiling ammonia just sufficient to dissolve it (an excess, as well as continued boiling, causes the liquid to turn brown), and filtered immediately at the boiling heat; the yellow crystals which separate from the dark filtrate when left at rest, are washed with cold water and recrystallised from hot water; their pale-yellow aqueous solution is mixed with strong hydrochloric acid; and the comenic acid, which is precipitated in the form of a white or pale yellow powder, is crystallised from boiling water.

Properties.—Comenic acid forms anhydrous prisms, laminæ, or granules, having a very faint yellowish colour, requiring more than 16 pts. of *boiling water* to dissolve them; sparingly soluble in *hydrated alcohol*, but insoluble in absolute alcohol.

Decompositions.—1. The acid, when subjected to dry distillation, behaves like meconic acid (Robiquet). When comenic (or meconic) acid is quickly heated in a retort, above the temperature of 200° to 220° C., at which pyromeconic acid would be formed, but not till complete carbonisation takes place, an acid yellowish watery liquid passes over, having a faint empyreumatic odour; and there remains a blackish grey, porous, carbonaceous mass, from whose ammoniacal solution, after filtration, hydrochloric acid throws down thick dark green flakes, which, if exposed to the air after washing with water, shrink up to a substance resembling *glance-coal* in appearance, and in its chemical relations agreeing perfectly with metagallic acid (Winckler, *Repert.* 59, 42).—2. Comenic acid suspended in water through which a stream of *chlorine gas* is passed, forms a solution of chlorocomenic acid, which crystallises out after a while, and oxalic acid, which remains in solution:

$$C^6H^4O^5 + Cl^2 = C^6H^3ClO^5 + HCl.$$

The oxalic acid and a brown colouring matter which forms during evaporation must be regarded as secondary products (How).—3. Similarly, the colourless solution of comenic acid in *bromine-water* yields bromocomenic acid which crystallises, and oxalic acid (How).—4. *Nitric acid*, even when very dilute, converts comenic acid into carbonic, hydrocyanic, and oxalic acids; and if the nitric acid is tolerably strong, and heated at the beginning of the action, the process is complete in a few minutes (How).—5. *Strong sulphuric acid* acts upon comenic acid in the same manner as on meconic acid. (Robiquet).—6. The acid dissolved in water and boiled with excess of *ammonia* till nearly all the ammonia evaporates, forms a black-red liquid, which, on cooling, deposits impure comenamate of ammonium as a grey viscid sediment. (How, p. 96.)

COMENATES.—Comenic acid is dibasic, forming neutral or normal salts, $C^6H^2M^2O^5$, and acid salts, $C^6H^3MO^5$. The neutral comenates of the alkali-metals cannot be obtained in the solid state.

Acid Comenate of Ammonium, $C^6H^3(NH^4)O^5$, is obtained in How's process for purifying comenic acid. The aqueous acid slightly supersaturated with ammonia, and evaporated in vacuo over oil of vitriol, yields four-sided prisms having a yellowish tinge; they give off 9·04 per cent. (1 at.) water at 100° C. (Stenhouse). The salt forms white square prisms having a very strong lustre; they redden litmus even when they separate on cooling from a hot solution of the acid in excess of ammonia. They do not give off anything at 177° C., but at 199°, in a sealed tube, they melt and are converted into a black mixture of charcoal and comenamate of ammonium; their aqueous solution is also converted into this salt by continued boiling with ammonia (p. 1100). They dissolve readily in boiling water, sparingly in alcohol. (How.)

Comenates of Barium. a. *Neutral.* $C^6H^2Ba^2O^5 + H^2O$ (at 121° C.).—Chloride of barium mixed with a solution of the acid in excess of ammonia throws down immediately—or in very dilute solutions, after some time only—yellowish quadratic needles united in concentric groups. These crystals do not lose water at 100° C., but at 121°, they give off 19·03 per cent. water, and if then heated to redness in the air, burn away in a fiery cloud. They do not dissolve in boiling water, but when boiled with it, are converted into a basic salt, which does not give off water at 121° C., and contains 54·5 per cent. baryta. (How.)

β. *Acid salt.* $C^6H^3CaO^5$ (at 100° C.).—The free acid does not precipitate barium-salts (Stenhouse). The salt is produced when baryta is boiled with excess of the acid. Chloride of barium mixed with a cold-saturated aqueous solution of the crystallised ammonium-salt immediately forms a crystalline precipitate, and with a more dilute solution, gradually deposits transparent crystals, which give off their 20·86 per cent. (somewhat more than 3 at.) water at 100° C., and melt at a stronger heat. (How.)

Comenate of Calcium. a. *Neutral.* $C^6H^2Ca^2O^5 + H^2O$ (at 121° C.)—The acid supersaturated with ammonia, precipitates from chloride of calcium, if the solutions are saturated, very short prisms which give off 18·20 per cent. ($\frac{5}{2}$ at.) water at 121° C., and when the solutions are dilute, small shining crystals, which at 121° give off 31·37 per cent. ($5\frac{1}{2}$ at.) water. The two kinds of crystals are insoluble in water, but become basic when boiled with water.

β. *Acid salt.* $C^6H^3CaO^5$ (at 121° C.)—A mixture of chloride of calcium and a cold saturated aqueous solution of the crystalline ammonia-salt, quickly deposits transparent, shining, rhombic crystals, which give off their water slowly at 100°, but the whole, amounting to 26·15 per cent. ($\frac{7}{2}$ at.) at 121°. They dissolve readily in boiling water, and crystallise therefrom on cooling.

Comenate of Copper. $C^6H^2Ca^2O^5 + H^2O$ (at 100° C.)—The dark green aqueous mixture of cupric sulphate and comenic acid (or the crystallised ammonium-salt, according to How) deposits, after a few minutes, elongated pyramids having the colour of Schweinfurt green. No acid comenate of copper appears to exist. (How.)

Comenates of Iron. Ferric Comenate. $Fe^2O^3.4C^6H^4O^5 + 3H^2O$, or [if $fe = \frac{2}{3}Fe$] $= fe^2O.4C^6H^3feO^5 + 5H^2O$ (at 100° C.)—Comenic acid imparts a bright red colour to ferric salts. The dark blood-red mixture of ferric sulphate with a cold-saturated solution of comenic acid or its ammoniacal salt, becomes paler by long standing, and deposits small pitch-black, shining, very hard, nearly tasteless crystals, which grate between the teeth, yield a dark brown powder, and dissolve slowly both in cold and in hot water, forming a pale red solution. (Stenhouse.)

The red mixture of aqueous comenic acid with ferric sulphate, becomes dark yellow at 65° C. (and gives off carbonic acid, according to How), by conversion of all the sesquioxide of iron into protoxide at the expense of the acid, part of which at first remains undecomposed, so that a fresh portion of ferric sulphate again produces reddening. This colour, however, disappears when the liquid is digested for twelve hours with excess of ferric sulphate, in consequence of the complete conversion of comenic acid into *another acid;* hence the no longer red liquid deposits small, pale yellow, shining crystals of a ferrous salt (probably ferrous oxalate, as the liquid contains oxalic acid, according to How), which burn away when heated, and dissolve sparingly in water; the acid of these crystals extracted by potash no longer reddens ferric salts. (Stenhouse.)

Comenate of Lead.—The acid and its ammonia-salt form with neutral acetate of lead a yellowish white granular precipitate, soluble in excess of comenic acid, but not in acetic acid. (Stenhouse.)

A lead-salt examined by Robiquet contained 54·1 per cent. oxide of lead.

Comenates of Magnesium. α. *Neutral.* $C^6H^2Mg^2O^5 + \frac{3}{2}H^2O$ (at 100° C.)—Sulphate of magnesium forms with the acid saturated with ammonia, especially when the mixture is stirred, hard, closely adhering, crystalline grains, consisting of short microscopic needles. These crystals heated to 100°, slowly give off 26·50 per cent. (4 at.) water; and if then kept at 121° for four days, they give off such a quantity [nearly $\frac{3}{2}$ at.] that the residual salt contains 21·30 per cent. magnesia, and is therefore not quite anhydrous. They are not soluble in boiling water. (How.)

β. The *acid salt,* $C^6H^3MgO^5 + H^2O$ (at 100° C.), crystallises, after a while, from a mixture of sulphate of magnesium with the cold-saturated solution of the crystalline ammonia-salt, in small rhombs, and from more dilute solutions, on evaporation, in larger crystals, which are strongly acid, give off 22·08 per cent. (3 at.) water at 116°, and dissolve readily in hot water. (How.)

Comenic acid does not precipitate *mercuric chloride.* (Stenhouse.)

Comenates of Potassium. α. *Neutral.* $C^6H^2K^2O^5$.—The aqueous acid half neutralised with potash, so as to form the mono-potassic salt, yields no precipitate, but when completely neutralised, deposits the sparingly soluble dipotassic salt. In this respect, comenic acid is opposite to meconic acid, the acid potassium-salt of which is the less soluble of the two. (Robiquet.)

β. *Acid salt.* $C^6H^3KO^5$.—The acid, dissolved in a slight excess of boiling potash-ley, yields crystals on cooling, which, after washing with cold water, crystallise from hot water in short, square, anhydrous needles, which redden litmus. (How.)

Comenates of Silver.—The *neutral salt,* $C^6H^2Ag^2O^5$, is obtained by exactly precipitating a solution of nitrate of silver with comenic acid neutralised with ammonia. The thick yellow precipitate does not detonate when heated. (Liebig.)

The *acid salt,* $C^6H^3AgO^5$, is the precipitate (white, granular, or flocculent, according to Stenhouse) which the free acid produces in solution of nitrate of silver. (Liebig.)

Comenate of Sodium.—The solution of the acid in tolerably strong boiling soda-ley yields, on cooling, nodules and prisms, which, after washing with a little cold water, crystallise from the smallest possible quantity of hot water, in acid, anhydrous, four-sided prisms, containing 17·09 per cent. soda, and therefore = $C^6H^3NaO^5$. (How.)

Comenates of Strontium.—The neutral and acid salts closely resemble the corresponding barium-salt, but are more soluble.

Substitution-derivatives of Comenic Acid.

BROMOCOMENIC ACID. $C^6H^3BrO^5$. (How, *loc. cit.*)—The colourless solution of comenic acid in a slight excess of bromine-water deposits, after a few hours, oily, colourless, shining, strongly refracting, four-sided prisms, which dissolve in water and in alcohol less easily than chlorocomenic acid; they give off their water of crystallisation at 100° C.

The acid is decomposed by *nitric acid,* yielding hydrobromic, carbonic, hydrocyanic, and oxalic acids. With *zinc* and *water* it decomposes like chlorocomenic acid.

Bromocomenic is dibasic, like comenic acid. The *acid bromocomenates of ammonium, potassium,* and *sodium* are crystallisable; the first crystallises in long needles. The neutral salts of these bases are not obtainable.

The *neutral bromocomenates of barium* and *calcium* are amorphous and insoluble; the *acid* salts are very easily soluble.

The solution of the acid in a slight excess of ammonia yields, with nitrate of silver, neutral *bromocomenate of silver* in the form of a yellow precipitate having the consistence of clay when dry; and the solution of the acid in warm water forms with nitrate of silver, flakes of the *acid salt*, $C^6H^2AgBrO^5$, which crystallises from boiling water in short shining prisms.

CHLOROCOMENIC ACID. $C^6H^3ClO^5$. (How, *loc. cit.*)—Obtained by passing chlorine through water in which pulverised comenic acid is suspended, washing the crystals which separate with cold water, and recrystallising from hot water,—or by passing chlorine into cold water saturated with acid comenate of ammonium; the liquid then acquires the colour of chlorine-water, and gradually deposits crystals of chlorocomenic acid, which increase on addition of hydrochloric acid, and may be purified as in the first process. The mother-liquor becomes continually browner, and still deposits brown crystals of the acid.

The crystals are long, colourless, shining, four-sided prisms, containing 12·47 per cent. ($\frac{3}{2}$ at.) water, which they give off at 100° C. They dissolve both in cold and in hot *water*, more readily than comenic acid; very easily in warm alcohol.

The acid melts when heated, blackens, gives off a large quantity of hydrochloric acid, and at last yields a small crystalline sublimate, probably consisting of paracomenic acid. By *nitric acid* it is quickly converted into hydrochloric, carbonic, hydrocyanic, and oxalic acids. Its aqueous solution, treated with zinc, slowly gives off hydrogen, and afterwards contains hydrochloric acid and oxide of zinc.

Chlorocomenic acid is dibasic, forming *neutral salts*, $C^6HM^2ClO^5$, and *acid salts*, $C^6H^2MClO^5$.

The *chlorocomenates* resemble the comenates, but dissolve more readily in water.

The acid chlorocomenates of ammonium, potassium, and sodium crystallise readily. The neutral salts are not obtainable.

The ammonium-salt forms with *chloride of barium* and *chloride of calcium*, bundles of needles which appear more or less quickly, according to the degree of concentration; with *sulphate of magnesium*, it gradually forms a few crystals; and with *cupric sulphate*, immediately, a crystalline precipitate. The neutral chlorocomenates of these bases appear to be all amorphous and insoluble.

The acid colours *ferric salts* deep red, like comenic acid.

Silver-salts. a. Neutral.—The acid dissolved in a slight excess of ammonia forms, with nitrate of silver, yellow amorphous flakes, which, after drying, resemble clay in appearance, consistence, and tenacity. The salt dried at 100° C. contains 56·85 per cent. silver, and is therefore $C^6HAg^2ClO^5$. When ignited in the air, it leaves silver, together with a small quantity of chloride of silver; when boiled with hydrochloric acid, it remains partly undecomposed. It is insoluble in boiling water, but dissolves in nitric acid, from which, if heated with the salt, it separates cyanide of silver.

b. Acid.—The warm aqueous acid added to solution of nitrate of silver throws down feathery crystals, which, after washing with cold water, separate from boiling water in short shining needles. These crystals give off 4·44 per cent. water at 100° C When ignited, they leave silver and chloride of silver.

ETHYLCOMENIC ACID. $C^8H^8O^5 = C^6H^3(C^2H^5)O^5$ (How, *loc. cit.*).—To prepare this acid, dry hydrochloric acid gas is passed through absolute alcohol in which pulverised comenic acid is suspended, till the acid dissolves, which takes place slowly; the clear liquid (which deposits nothing on addition of water) is evaporated at a temperature below 100° C.; the crystalline residue is maintained at this temperature, till it no longer smells of hydrochloric acid, and then left to crystallise by cooling from its solution in water at nearly 100°. Or, pulverised comenic acid, heated with alcohol and iodide of ethyl in a closed vessel to a temperature above 100°, forms a granular deposit consisting of an acid not yet examined, and ethylcomenic acid, in needle-shaped crystals, which may be separated and purified by recrystallisation. Similar products are obtained by heating a mixture of comenic acid, alcohol, and chloride of amyl to 160° for 12 hours.

The acid forms large square needles, which begin to evaporate at 100° C.; melt at 135° into a clear brown-red liquid, which solidifies again in the crystalline form on cooling; and if kept for a longer time at 135°, sublime in long flat unaltered needles, having the same composition. It is very soluble in water and alcohol, and reddens litmus; the aqueous solution coagulates albumin.

The acid may be boiled for a short time without alteration, but if boiled for a longer time, it yields free comenic acid. With aqueous solutions of the fixed alkalis, even in the cold, it very quickly forms salts, and yields free alcohol.

When ammoniacal gas is passed through a solution of the acid in absolute alcohol, the *ammonia salt* is deposited in yellow silky bundles of needles, which give off ammonia in dry air, and almost completely in vacuo over oil of vitriol, leaving ethylcomenic acid.

The acid imparts a deep red colour to *ferric salts*. Its *silver-salt* is gelatinous, and decomposes very quickly, even in the dark.

COMPTONITE. See THOMSONITE.

CONCENTRATION. A process which has for its object to increase the amount of a dissolved substance in a liquid, relatively to the quantity of the solvent, without adding any more of the dissolved substance itself. When the solvent is volatile, this object is effected by evaporation, as when water, alcohol, or ether is expelled from a solution by heat, by exposure to the air, or in vacuo. If the dissolved substance is more volatile than the solvent, the concentration is effected by distillation, the more concentrated liquid being then found in the distillate, as in the rectification of hydrated alcohol and of volatile oils dissolved in water. In the case of aqueous liquids, concentration is sometimes effected by freezing out the water; in this manner, a strong solution of salt may be obtained from sea-water; strong spirit from vinous liquids, &c.

A similar principle is applied to the separation of silver from lead. The argentiferous lead is melted and left to cool, till about two-thirds of the mass is solidified; this consists of nearly pure lead, the portion which still remains liquid being an alloy richer in silver than the original mass. By repeating this operation several times, the alloy at last becomes sufficiently rich in silver to be treated by cupellation.

CONCHIOLIN. An organic constituent of the shells of certain molluscs, first observed by Frémy. It closely resembles keratin, or epidermose; does not yield gelatin by boiling with water, even under strong pressure; is insoluble in water, alcohol, ether, acetic acid, dilute mineral acids, and potash-ley. It contains 50 per cent. carbon, 6 hydrogen, and 16 to 16·7 nitrogen, a composition very near to that of epidermose: whether it contains sulphur does not appear to have been made out. A similar substance, but containing only 12 or 13 per cent. nitrogen, was found by Schlossberger in the byssus of acephalous molluscs.

CONCRETIONS, ANIMAL. This term is applied to all deposits in the animal body which are destitute of distinct organic structure. They are almost always of morbid character, a few only, as the brain-sand (the sabulous matter of the pineal gland), the crystals in the auditory organs of most animals, and in the vertebral column of frogs, appearing to occur in healthy animals.

Concretions are formed:—1. In the liquid secretions, as urinary, salivary, and biliary calculi, concretions in the stomach and intestines, in the lachrymal ducts, the cavity of the nose, the sebaceous glands of the skin (gouty concretions), &c.—2. In the cellular tissue of the organs, as in the brain, heart, veins, lungs, and indeed in all parts of the body. These latter are formed by the gradual transformation of other morbid products the animal matter of which is gradually absorbed, while the inorganic substance remains, and is often increased by addition of fresh deposits. All concretions of this kind have a very similar, indeed almost identical, constitution, consisting of a base sometimes predominant, sometimes subordinate, of coagulated fibrin, with deposits of phosphate and carbonate of calcium, ammonio-magnesian phosphate and carbonate of magnesium, in variable proportions. Another class of concretions allied to those last mentioned, are the so-called asteromatose deposits in the coatings of the arteries, especially of the aorta. They are sometimes, but not always, associated with calcareous deposits, and form layers of yellowish-white colour, and very slight consistence. They consist mainly of crystalline deposits of cholesterin.

The essential constituents of animal concretions are.

Uric acid and its salts.
Xanthin and cystin.
Hippurates and benzoates.
Cholesterin and fat.
Bile-pigment or cholochrome.
Fibrin.
Phosphate of calcium; ammonio-magnesian phosphate; oxalate of calcium; carbonate of magnesium.

The following substances occur as cements or less essential constituents: urinary and gall-bladder mucus, albumin, blood-red, the biliary acids, animal matter of indeterminate character, and sometimes soluble salts.

The chemical analysis of animal concretions must always be preceded by an examination of their physical structure. They are very often made up of concentric layers of substances differing in chemical constitution, so that it becomes necessary to make a separate analysis of each layer.

As respects their behaviour when heated, concretions are distinguished as—1. *Perfectly combustible.*—2. *Partially combustible.*—3. *Incombustible.* Their special chemical characters are given in the following tables. (Handw. d. Chem. ii. [2] 171.)

1. *Stones which burn without residue when heated on platinum-foil.*

a. The nitric acid solution is coloured red by ammonia, after evaporation.		*b*. The nitric acid solution is *not* coloured red by ammonia, after evaporation.		The substance burns with a bright flame.		The substance has a brown colour, is friable, like ochre, and burns with an animal odour.	
α. Does not give off ammonia when treated with potash.	β. Gives off ammonia when treated with potash.	Turns yellow on evaporation; insoluble in carbonate of potassium.	Turns dark brown on evaporation; soluble in ammonia and in carbonate of ammonia, crystallising from the former solution in microscopic six-sided tables.	Has a distinct crystalline texture; dissolves with aid of heat in alcohol, and crystallises from the solution, on cooling, in nacreous laminæ. Insoluble in caustic potash.	Emits, in burning, the odour of burnt horn, and swells up. Soluble in caustic potash, precipitated from the solution by acetic acid; soluble in excess of acetic acid, and then precipitable by ferrocyanide of potassium.	Sparingly soluble in alcohol and in water; soluble, with dark brown colour, in potash, the solution exhibiting, with nitric acid, the variations of colour characteristic of cholochrome.	Soluble in alcohol. The solution has a bitter taste, and exhibits a splendid violet-red colour with sugar and sulphuric acid.
Uric Acid.	**Urate of Ammonia.**	**Xanthin.**	**Cystin.**	**Cholesterin.**	**Fibrin.**	**Cholochrome.**	**Biliary Acids.**

2. *Stones which leave a considerable residue when heated on platinum-foil.*

1. The residue melts easily before the blowpipe.		2. The residue does not melt before the blowpipe.			3. The substance gives, with nitric acid and ammonia, the reaction of uric acid, but leaves a residue when ignited.			
α. Does not effervesce with acids, either before or after ignition; soluble in hydrochloric acid; precipitable by ammonia; precipitated by oxalate of ammonia. Black-brown enamel with cobalt-solution.	β. Gives off the odour of ammonia when heated; soluble without effervescence in acetic acid, and precipitated from this solution in the crystalline form by ammonia. Dark red glass with cobalt-solution.	α. Residue white, not alkaline; in other respects exhibiting the behaviour of neutral phosphate of calcium.	β. The fresh substance not attacked by acetic acid. Soluble without effervescence in mineral acids, and precipitated by ammonia; residue alkaline; effervesces with acids.	γ. Emits a strong white light when ignited; effervesces with acids before ignition; precipitated from the neutralised solution by oxalate of ammonia.	α. Melts before the blowpipe, and colours the flame deep yellow.	β. Behaves like α, excepting that it does not colour the flame yellow. Its solution in hydrochloric acid gives a yellow precipitate with dichloride of platinum.	γ. Infusible before the blow-pipe, and behaves, after ignition, like carbonate of calcium.	δ. Infusible before the blowpipe. The residue dissolves, with slight effervescence, in dilute sulphuric acid, and is precipitated from this solution by potash or by ammonio-sodic phosphate.
Neutral Phosphate of Calcium.	**Ammonio-magnesian Phosphate.**	**Basic Phosphate of Calcium.**	**Oxalate of Calcium.**	**Carbonate of Calcium.**	**Urate of Sodium.**	**Urate of Potassium.**	**Urate of Calcium.**	**Urate of Magnesium.**

CONDENSATION. This term, in its most general sense, implies increase of density, but it is often restricted to the passage of a gas to the liquid or solid state.

CONDRODITE. See CHONDRODITE.

CONDURRITE. A mineral containing copper and arsenic, originally obtained from the Condurrow mine near Helstone, in Cornwall; since found in the Huel Druid mine, near Redruth; also in mines at Coquimbo and Copiapo, Chili. It forms amorphous, roundish, flattened nodules, with flat conchoïdal fracture, brownish-black colour, bluish-black on the outer surface, opaque, dull or with glimmering lustre; streak metallic; powder brownish-black; soft. Specific gravity, 4·2—5·2.

Condurrite has been frequently analysed, but with very variable results; in fact it appears to be a mixture resulting from the alteration of Domeykite (Cu^6As), and mainly consisting of a hydrated cuprous arsenite mixed with small quantities of manganese, sulphur, iron, and silica. (Kopp, Handw. d. Chem. ii. [3], 173.)

CONGLOMERATE. A geological term applied to masses of rounded fragments of older rocks held together by a cement; if, on the other hand, the fragments are for the most part sharp-edged, the mass is called breccia. Conglomerates are distinguished as quartzose, calcareous, dolomitic, granitic, syenitic, &c., according to the nature of the component fragments: the cement may be siliceous, calcareous, or argillaceous.

ADDENDA.

ACETYLENE. C^2H^2. A gaseous hydrocarbon, which appears to have been first obtained by E. Davy (Records of gen. Sci. Nov. 1836; Gm. viii. 150), though in an impure state, by the action of water on the black substance which passes over in the preparation of potassium; but its preparation in the pure state, and indeed the establishment of its existence as a definite compound, is due to Berthelot (Institut, 1859, p. 410; 1860, p. 565; Rép. Chim. pure, ii. 222; Ann. Ch. Pharm. cxv. 116), who obtained it by passing ethylene-gas, or the vapour of ether, alcohol, aldehyde, or wood-spirit, through a red-hot tube, and by the action of red-hot copper on chloroform. Ether yields it in largest quantity, but by whichever of the preceding methods it is produced, it is always mixed with a considerable quantity of other gases, and requires to be purified by passing the gaseous mixture into an ammoniacal solution of cuprous chloride; a red precipitate is then formed which, when decomposed by hydrochloric acid, yields pure acetylene.

Berthelot has further shown that acetylene is one of the constituents of coal-gas, and that it may be formed by the direct combination of carbon and hydrogen, viz. by passing hydrogen gas over charcoal, heated to whiteness by the passage of the electric arc.

Acetylene is also produced: *a.* By the action of alcoholic potash on monobromethylene (vol. ii. 569), $C^2H^3Br - HBr = C^2H^2$ (Sawitsch, Compt. rend. lii. 157), or on bromide of monobromethylene ($C^2H^3Br^3$), bromacetylene, C^2HBr, being formed at the same time (Reboul, Ann. Ch. Pharm. cxxiv. 267).—*b.* By passing the vapour of monobromethylene into an ammoniacal solution of nitrate of silver, in which case a precipitate is formed consisting of the silver-compound of acetylene $C^2H^2Ag^2$ (more probably C^2HAg), which, when treated with dilute hydrochloric acid, yields acetylene (Miasnikoff, Ann. Ch. Pharm. cxviii. 330).—*c.* By heating monobromethylene with ethylate or amylate of sodium, the products being bromide of sodium, ethylic or amylic alcohol, and acetylene. (Sawitsch, see vol. ii. p. 569.)

$$\underset{\text{Bromethylene.}}{C^2H^3Br} + \underset{\substack{\text{Amylate of}\\ \text{sodium.}}}{C^5H^{11}NaO} = NaBr + \underset{\substack{\text{Amylic}\\ \text{alcohol.}}}{C^5H^{12}O} + \underset{\text{Acetylene.}}{C^2H^2}.$$

d. When a mixture of marsh-gas and carbonic oxide is passed through a red-hot tube. (Odling.)

$$CH^4 + CO = C^2H^2 + H^2O.$$

Acetylene is a colourless gas of specific gravity 0·92, having a peculiar and unpleasant odour, moderately soluble in water, not condensed by cold or pressure. It burns with a very bright and smoky flame, 1 vol. acetylene consuming 2½ vol. *oxygen*, and producing 2 vol. carbonic anhydride. When mixed with *chlorine*, it detonates almost instantly, even in diffused daylight, with separation of charcoal.

Acetylene unites with *copper* and with *silver*, forming detonating compounds, which are produced on passing the gas into the ammoniacal solutions of cuprous chloride and nitrate of silver respectively. The copper-compound is red, the silver-compound grey; both are decomposed by hydrochloric acid, with separation of acetylene. Acetylene mixed with air, and in presence of moisture, rapidly attacks metallic copper. The gas is absorbed and the copper becomes coated with a black deposit which explodes violently when heated. The formation of this substance (acetylide of copper mixed probably with cuprous oxide) is doubtless the cause of the dangerous explosions which sometimes occur in the cleaning out of copper gas-mains after long use. (Crova, Compt. rend. lv. 435; J. pr. Chem. lxxxvii. 124.)

Acetylene unites with *nascent hydrogen*, and is converted into ethylene C^2H^4. This change is brought about by subjecting the copper-compound of acetylene to the action of hydrogen evolved by the action of zinc on aqueous ammonia; the hydrogen evolved from acid liquids does not produce this reaction.

Acetylene unites, like ethylene, with *bromine*, *sulphuric acid*, and the elements of *water*, forming with bromine the compound $C^2H^2Br^2$, with sulphuric acid, acetyl-sulphuric acid $C^2H^2.H^2SO^4$, and with the elements of water, acetyl-alcohol $C^2H^2.H^2O = C^2H^4O$. (Berthelot.)

Acetyl-sulphuric acid, $C^2H^4SO^4$, is produced by brisk and long-continued agitation of acetylene with strong sulphuric acid. If the liquid be then carefully diluted, saturated with carbonate of barium, and the filtrate evaporated, acetyl-sulphate of barium is obtained in crystals. (Berthelot.)

Acetylic alcohol, $C^2H^4O = C^2H^2.H.O$, is obtained by distilling and rectifying the acid liquid just mentioned, as an easily decomposible liquid resembling acetone, but having an extremely pungent odour. It is somewhat more volatile than water, and is separated therefrom by carbonate of potassium, but apparently not by chloride of calcium. (Berthelot.)

Bromacetylene. C^2HBr. (Reboul, Compt. rend. lv. 136.)—Produced by the action of alcoholic potash on dibromide of dibromethylene:

$$C^2H^2Br^2.Br^2 - HBr - Br^2 = C^2HBr.$$

Also, together with acetylene and dibromethylene, by the action of boiling alcoholic potash on dibromide of monobromethylene.

$$\begin{array}{llll} C^2H^3Br.Br^2 & - \quad HBr & = & C^2H^2Br^2. \\ & & & \text{Dibromethylene.} \\ C^2H^2Br^2 & - \quad HBr & = & C^2HBr. \\ & & & \text{Bromacetylene.} \\ C^2HBr.Br^2 - HBr & - \quad Br^2 & = & C^2H^2. \\ & & & \text{Acetylene.} \end{array}$$

It is spontaneously inflammable, liquefies under a pressure of three atmospheres, is soluble in water, and very soluble in dibromethylene, whereas acetylene is much less soluble in that liquid. This property may be rendered available for the separation of acetylene and bromacetylene.

It unites with *bromine*, forming the dibromide of bromacetylene, $C^2HBr^3 = C^2HBr.Br^2$. When passed into ammoniacal solution of cuprous chloride, it yields a precipitate of cuprosacetylene, C^2HCcu:

$$C^2HBr + 3Cu^2Cl = C^2HCcu + CuBr + 3CuCl;$$

which, when treated with hydrochloric acid, yields a gas having the composition and most of the properties of Berthelot's acetylene, but differing somewhat in its behaviour to bromine, with which it yields the compound $C^2H^2Br^4$, and a small quantity of C^2HBr^3.

ALLYLENE. C^3H^4. This compound, homologous with acetylene, is produced, in like manner, by the action of ethylate of sodium on monobromotritylene, C^3H^5Br. The materials are made to react in a well-cooled, sealed flask, and on opening the vessel, a large quantity of gas escapes, which, when passed into an ammoniacal solution of cuprous chloride, produces a yellow precipitate. This precipitate decomposed by hydrochloric acid yields pure allylene, a colourless gas, having an unpleasant odour, burning with a smoky flame, and forming with *mercurous salts* a dark grey precipitate, and with *silver salts* a white precipitate which detonates when heated. The copper compound above mentioned burns with a reddish flame, and is decomposed with incandescence by bromine. (Sawitsch, Compt. rend. lii. 399; Ann. Ch. Pharm. cxix. 185.)

Allylene is also produced by passing the vapour of bromotritylene into a hot concentrated alcoholic solution of potash. The gas thus evolved forms in ammoniacal silver-solution, a precipitate consisting of a dark yellow compound, *silver-acetylene*, and a heavier white compound which is *silver-allylene*, $C^3H^4Ag^2$. The gas evolved from this compound by the action of hydrochloric acid, forms with bromine an oily liquid, which boils, with partial decomposition, between 180° and 200° C., and has the composition of a mixture of $C^3H^4Br^2$ and $C^3H^4Br^4$. (Morkownikoff, Bull. Soc. Chim. 1861, p. 90.)

CÆSIUM. *Symbol*, Cs. *Atomic weight*, 133.—A metal belonging to the same group of elements with lithium, sodium, potassium and rubidium. Its existence was detected in 1860 by Kirchhoff and Bunsen, by help of the method of *spectral analysis* which they introduced (see SPECTRUM, SPECTRAL ANALYSIS). The compounds of cæsium so closely resemble the corresponding compounds of potassium and rubidium, that no difference can be perceived between them by ordinary analytical means; but in the spectrum-apparatus a few thousandths of a milligramme can easily be detected. The most characteristic lines in the cæsium-spectrum are two blue lines Cs α and Cs β, in the neighbourhood of the strontium-line, Sr δ; they can be clearly seen, even with silicate of cæsium, and the name *Cæsium*, from *cæsius*, sky-blue, has been chosen as recalling their colour.

Cæsium has not yet been found, except in company with rubidium (see Rubidium), and it occurs in even still smaller quantities than the latter element. Cæsium was first detected in the Dürkheim mineral water, ten kilogrammes of which contain not quite two milligrammes of chloride of cæsium. Kreuznach water contains less, and in the lepidolite of Rozena (which is the principal source of rubidium) only insignificant traces of it are found. (Kirchhoff and Bunsen, Pogg. Ann. cxiii. 353; Jahresber. 1861, 177.)

The most abundant source of it yet discovered appears to be the lepidolite of Hebron, in Maine, U.S. This mineral occurs there in large quantity in a coarsely crystalline granite, associated with red and green tourmaline and albite. It has a granular, and at the same time foliated crystalline structure, a pale rose to violet colour, and very closely resembles the lepidolite of Penig, in Saxony, and, like that, is also associated with the rare species, amblygonite. It contains rather more than 0·3 per cent. of cæsium, and as much rubidium as the lepidolite of Rozena. (O. D. Allen, Phil. Mag. [4] xxv. 189.)

Cæsium has also been found, in comparatively large quantity, in the mineral waters of Baden-Baden (Bunsen), Bourbonne-les-Bains, Haute-Marne (Grandeau, Ann. Ch. Phys. [3] lxvii. 177), in the *salines* of Aussee, and in the lithium-mica of Zinnwald (Schroetter, Wien Akad. Ber. xliv. 218). It exists in perceptible, but generally very small, quantities, in several other minerals, as triphyline (Blake, Sill. Am. J. [2] xxxiii. 274; Grandeau), carnallite (Erdmann), petalite (Grandeau), in the mineral water of Vichy (Grandeau), in those of Topusco and Lassinja (Schneider, Wien Akad. Ber. xlv. 483), and in the *salines* of Ebensee. (Redtenbacher, *ibid.* xliv. 153.)

The separation of cæsium from sodium and potassium depends upon the exceedingly slight solubility in water of its chloroplatinate. In order to obtain it pure, it is precipitated, together with chloride of potassium and chloride of rubidium, by means of chloride of platinum, from the mother-liquor, freed from everything except alkaline salts, obtained by the evaporation of Dürkheim water (Bunsen operated with the residue of about 40,000 kilogrammes of water); the precipitate is boiled with a *very small* quantity of water, allowed to settle, and the still hot solution decanted; when this operation has been repeated twenty times, the mixture of chloroplatinates of cæsium and rubidium which remains undissolved is reduced by heating in a stream of hydrogen, and the chlorides of those metals are extracted from the residue by boiling water. To separate the rubidium, the chlorides are transformed into carbonates, and the dry mixture of salts repeatedly exhausted with absolute alcohol, in which carbonate of cæsium is soluble, but carbonate of rubidium insoluble. As the carbonate of cæsium so obtained may still contain small quantities of potassium and rubidium, it must, for complete purification, be treated with sufficient baryta-water to render about four-fifths of it caustic, evaporated in a platinum dish, and the residue extracted with the smallest possible quantity of alcohol, which dissolves hydrate of cæsium, but leaves the carbonates of potassium and rubidium behind. When this operation has been repeated until the product, examined in the spectrum-apparatus, no longer gives the potassium and rubidium reactions, or gives them only very faintly indeed, the further treatment of it is found not to alter its equivalent weight; although the salt thus obtained is still a mixture of the chlorides of cæsium and rubidium, and not pure chloride of cæsium, as Bunsen at first supposed (*vid. infr.*).

The following process is given by Allen (*loc. cit.*) for the extraction of cæsium from the lepidolite of Hebron. Ten parts of the mineral, pulverised until it will pass through a sieve of 20 holes to the linear inch, are mixed with forty parts of coarsely powdered quicklime; a quantity of water sufficient to slake the lime is next mixed with as much hydrochloric acid as will convert from six to seven parts of the lime into chloride of calcium; the two mixtures are then united, and stirred vigorously during the slaking, thus intimately blending the mineral with suitable proportions of dry hydrate of lime and chloride of calcium. The mixture is put into Hessian crucibles, and heated to redness for six or eight hours (a shorter time would probably suffice). During the ignition, care must be taken to prevent the heat rising much above redness, as loss would then occur by volatilisation of the alkaline chlorides, and by the fusion of the mass and its consequent absorption into the crucibles. The product of this operation is detached from the crucibles, and boiled with water till all but a trace of the chlorides is removed. The solution thus obtained, containing chloride of calcium and alkaline chlorides, is evaporated till crystals begin to form; sulphuric acid is then added as long as sulphate of calcium separates, excess of acid being avoided, and the whole mass is evaporated to dryness, and strongly heated, to expel free hydrochloric acid. The residue is treated with water, the small quantity of sulphate of calcium which passes into solution is precipitated by carbonate of ammonium, the precipitate is filtered off, and the filtrate is again evaporated to dryness and ignited. In this way a mixture of the chlorides, containing also small quantities of the sulphates, of sodium, lithium, potassium, rubidium, and cæsium is obtained, from which the chlorides of the last two metals can be separated by treatment with bichloride of platinum as directed by Bunsen.

For the separation of cæsium from rubidium, Allen recommends the following process. The chlorides of the two metals are converted into sulphates, and then into carbonates, by precipitating with caustic baryta and saturating the solution with carbonic acid. From the carbonates, the acid tartrates are prepared by adding to the solution twice as much tartaric acid as is necessary to neutralise it, and these salts can then be separated from each other by fractional crystallisation: acid tartrate of rubidium requires for solution about eight times as much water as does acid tartrate of cæsium, and therefore crystallises out first, while the latter salt accumulates in the mother-liquors. The salts of the two alkalis may be thus separated from each other so completely that neither shows any trace of the presence of the other when examined with the spectroscope.

Pure **metallic cæsium** has not yet been obtained, but an amalgam of cæsium can be easily procured by electrolysing a solution of chloride of cæsium, using mercury as the negative pole. Cæsium-amalgam decomposes water in the cold, and when exposed to the air, gets hot and covers itself with a coating of deliquescent hydrate of cæsium. When cæsium-amalgam is connected with potassium-amalgam or with rubidium-amalgam and water, so as to form a galvanic circuit, it shows itself to be more electropositive than either of them; cæsium is therefore the most electropositive element yet known.

Bromoplatinate of Cæsium readily separates, together with the rubidium-salt, when dibromide of platinum is added to a dilute solution of the chlorides of the two metals. If potassium is present, the bromoplatinate of that metal is carried down likewise. (Allen.)

Carbonate of Cæsium, $Cs^2CO^3 + aq.$—Confusedly developed crystals, which give an anhydrous sandy powder when heated. Dissolves in 9·1 pts. absolute alcohol at 19° C., and in 5 pts. at 78·4° C.; very caustic; deliquesces in the air and gradually becomes converted into acid carbonate; dissolves in water in nearly all proportions with the aid of heat.

Acid carbonate of Cæsium, $CsHCO^3$.—Tolerably well-formed, but not measurable prismatic crystals, permanent in the air, of a glassy lustre. Reacts hardly alkaline; by ignition it is easily changed into the neutral salt.

Chloride of Cæsium, $CsCl$.—Crystallises in cubes, which deliquesce in the air like chloride of lithium, and can thereby be distinguished from chloride of potassium or of rubidium. When gently ignited, chloride of cæsium easily melts; it is somewhat volatile, and in the air easily becomes somewhat alkaline. (Bunsen.) According to Johnson and Allen pure chloride of cæsium is not deliquescent.

Chloroplatinate of Cæsium, $CsCl\,PtCl^2$.—Bright yellow sandy powder, composed of shining, transparent, microscopic regular octahedrons. It is more difficultly soluble than the chloroplatinate of either potassium or rubidium; the following table gives the solubility in 100 pts. water of the three salts, as determined by Bunsen, the

Temperature.	Potassium-salt.	Rubidium-salt.	Cæsium-salt.
0° C.	0·74	0·184	0·024
10	0·90	0·154	0·050
20	1·12	0·141	0·079
30	1·41	0·145	0·110
40	1·76	0·166	0·142
50	2·17	0·203	0·177
60	2·64	0·258	0·213
70	3·19	0·329	0·251
80	3·79	0·417	0·291
90	4·45	0·521	0·332
100	5·18	0·634	0·377

cæsium-salts having been purified by the first process, and therefore still containing a little rubidium.

Hydrate of Cæsium, CsHO + aq.—Confusedly crystallised, deliquescent, exceedingly caustic. At a red heat it does not become anhydrous; it attacks platinum, is entirely volatile when heated on a platinum wire, and is easily soluble in alcohol.

Nitrate of Cæsium, $CsNO^3$.—Contains no water of crystallisation, is isomorphous with nitrate of rubidium and not with nitrate of potassium. The crystals are hexagonal prisms combined with the hexagonal pyramid. P : P in the terminal edges = 142° 56′; in the lateral edges = 78° 58′. Rates of axes, 1 : *c* = 1 : 0·7135.

$$P \,.\, \infty P \,.\, P2 \,.\, \infty P2 \,.\, 0P \,.\, \tfrac{3}{4}P.$$

The salt has a cooling saline taste, like that of saltpetre, and is soluble in ten times its weight of water at 3° C. (Bunsen.)

Picrate of Cæsium resembles the corresponding potassium-salt. It cannot be separated from picrate of rubidium by crystallisation. (Allen.)

Sulphate of Cæsium, Cs^2SO^4, forms anhydrous, ill-defined, hard crystals, grouped together in bunches, and permanent in the air. One part of the salt dissolves in 0·63 pts. of water at − 2° C. (1 pt. of sulphate of potassium dissolves in 12·5 pts. of water at the same temperature.)

Sulphate of cæsium forms double salts with sulphate of magnesium, sulphate of cobalt, &c., belonging to the type $KMgSO^4 + 3H^2O$, and is isomorphous with the corresponding potassium- and ammonium-compounds. $CsCoSO^4 + 3H^2O$, shows the following surfaces: $0P \,.\, \infty P \,.\, +P \,.\, [P\infty] \,.\, +2P\infty \,.\, \infty P2$. Sulphate of cæsium forms, with sulphate of aluminium, an alum crystallising in regular octahedrons of a glassy lustre. (Bunsen, Ann. Ch. Pharm. cxix. 111.)

Acid tartrate of Cæsium, $C^4H^5CsO^6$.—Colourless, transparent, flattened prisms, which do not diminish in weight when pulverised and dried at 100°. One part of this salt dissolves in 1·02 pts. of boiling water, or in 10·32 pts. of water at 25° C. (Allen.) The *neutral tartrate* is very deliquescent. (Bunsen.)

Atomic weight of Cæsium.—The atomic weight of cæsium has been determined by the analysis of its chloride. This salt, purified from chloride of rubidium by means of chloride of platinum in the manner already described, was found by Bunsen to contain:—

	Chlorine.	Cæsium.
After the 1st purification, ...	22·334	77·666
„ 2nd „	22·334	77·666
„ 3rd „	22·316	77·684

whence he deduced 123·4 for the atomic weight of cæsium. Subsequent experiments by Johnson and Allen (Phil. Mag. [4] xxv. 196) have shown that the chloride of cæsium used for these determinations still contained chloride of rubidium, and that the atomic weight calculated from them is consequently too low. Their analyses of chloride of cæsium, prepared from the acid tartrate purified by concentrating its solution and recrystallisation, gave the following results:—

	Chlorine.	Cæsium.
I.	21·044	78·956
II.	21·031	78·969
III.	21·043	78·957
IV.	21·063	78·937

Bunsen has since published new determinations (Pogg. Ann. cxix. 1) which agree very closely with these. The chloride of cæsium used for them was prepared by the following process, from a mixture of the chlorides of cæsium and rubidium which had been previously completely freed from potassium, sodium, and lithium. The chlorides were first converted into carbonates, and then a little more tartaric acid was added to the solution than was needed to convert the cæsium into neutral tartrate and the rubidium into the acid salt (the quantity of acid requisite being deduced from a preliminary determination of the amount of chlorine in the mixed chlorides). The liquid was next evaporated to dryness, and the powdered saline mass exposed to moist air in a funnel stopped with a small filter. In this way a solution of the very deliquescent tartrate of cæsium was obtained, while the acid tartrate of rubidium remained as a solid salt in the funnel. The tartrate of cæsium was converted into chloride, precipitated with bichloride of platinum, the precipitate washed and decomposed by heating in a stream of hydrogen, and this process was repeated until the proportion of chlorine in the resulting chloride of cæsium did not alter any longer. The product so prepared gave—

	Chlorine.	Cæsium.
After the 4th purification, ...	21·057	78·943
" 5th "	21·045	78·955
" 6th "	21·052	78·948

Taking Ag = 107·94 and Cl = 35·46 (Stas), the mean of Johnson and Allen's experiments gives 133·03 for the atomic weight of cæsium, while the mean of Bunsen's most recent experiments gives 132·99, so that we may take Cs = 133·0 as being very near the truth.

On the spectrum of cæsium, see Johnson and Allen (Phil. Mag. [4] xxv. 199), and Bunsen (Pogg. Ann. cxix. 6).—G. C. F.

Critical Opinions of this Dictionary.

The DAILY NEWS.

'Chemistry is making rapid strides; it is fast growing into a great philosophy; already a colossal structure, its wings are extending in every direction. For many years materials accumulated faster than the builders could put them together, but latterly great efforts have been made; rough work has been improved by help of superior tools; mathematical influence has aided in giving beauty to its lines; much of the coarse front, which truly was only scaffolding, has been removed, and a grand edifice has been unfolded to view. WATTS's *Dictionary of Chemistry* is the first complete handbook of the fabric. . . . In these volumes, Mr. WATTS, who seems to have done more than half the work himself, has successfully brought together our whole stock of chemical knowledge. Every manufacturer interested in chemistry—and what manufacturer is not?—every dealer in chemical products—and what material products are not chemical?—every medical practitioner anxious to assist in superseding the present empirical practice of physic by a rational system of therapeutics, every geologist and mineralogist, every follower of pharmacy, every gentleman who has a library, should possess this excellent work of reference.'

The CHEMIST and DRUGGIST.

'We notify the conclusion of the splendid work upon which Mr. HENRY WATTS, F.R.S. has been so long engaged. The fifth and last volume of the *Dictionary of Chemistry* has been completed, and we can now form an adequate conception of the vast extent of the region of fact and theory that has been so minutely surveyed by the industrious and learned editor. The complete work comprises more than five thousand large pages of closely printed matter, and has been well described by a contemporary as a truly magnificent work, almost German in the cyclopædic comprehensiveness of its science, and thoroughly English in its practical usefulness. Between the first and last articles, *Abichite* and *Zymurgy*, every chemical substance now known is described, generally with great fulness, and always with ample reference to the original sources of information. Mineralogy, crystallography, and all those branches of physics which are connected with chemistry, come within the scope of the work. Though the editor has written the greater part of the dictionary, he has enjoyed the assistance of twenty-one eminent scientific men, who have contributed articles of great interest and utility. The essays on subjects connected with chemical theory by Dr. ODLING and Prof. G. C. FOSTER; the articles on the practical applications of chemistry by Dr. PAUL; those on subjects connected with physiology by Dr. MICHAEL FOSTER; and the various contributions by Dr. FRANKLAND, Dr. WILLIAMSON, Dr. HOFMANN, and other great chemists, on subjects which they have made their own, have greatly enriched the work. We sincerely hope that the success of this incomparable scientific production may be commensurate with the expectations of the publishers.'

The ATHENÆUM.

'MODERN chemistry is most fully, indeed most elaborately, displayed in these volumes. The student of this useful science, which advances our knowledge of Nature by shewing us many of the transmutations of matter, until it becomes excited with the ever mysterious energy, Life, cannot find another book so full of information as this one upon all that belongs to chemical philosophy. The manufacturer who desires to avail himself of the facts which this science has established, and thus to improve his special industry, cannot go to a purer source of information than this. Technical teaching is just now engaging serious attention. Technology necessarily, therefore, forms an important portion of any book devoted to chemistry, which is so especially a science for practical application. Mr. WATTS and the high-class Contributors by whom he has been assisted have not forgotten this; therefore, applied chemistry in all its branches has received most satisfactory treatment at their hands. That select division of the public who are desirous of obtaining as much information as possible respecting the advances of human knowledge by the labours of experimental philosophers, cannot refer to any work of more completeness than this in all that belongs to chemistry and the allied branches of other sciences. These volumes shew how vast are the accumulations of facts in the division of ORGANIC CHEMISTRY, what a rich store of material has been gathered together, and how perfect are many of the parts which now exist in fragmentary beauty.'
